Abstract

Current state-of-the-art correct-by-design controllers are designed for full-state measurable systems. This work first extends the applicability of correct-by-design controllers to partially observable LTI systems. Leveraging 2nd order bounds we give a design method that has a quantifiable robustness to probabilistic disturbances on state transitions and on output measurements. In a case study from smart buildings we evaluate the new output-based correct-by-design controller on a physical system with limited sensor information.

Key words: Correct-by-design controller synthesis, Output-feedback, Stochastic disturbances

1 Introduction

Reliable and autonomous operation of many complex engineering systems demands guaranteed behaviour over the full spectrum of operating conditions. This is the case with applications in avionics, automotive, transportation systems, dependable electronics, semiconductors [14], and in general in systems where safety is critical and where mistakes lead to impactful economical losses.

Within the computer sciences, verification and synthesis of critical hardware and software has been attained in the industrial practice by tools and techniques from the domain of formal methods [4]. Employing well-structured specifications, such as properties expressed over linear-time temporal logics (LTL), automated and computer-aided tools have been developed for the verification and synthesis of models of the systems of interest. To meet new demands from domains dealing with complex new applications, these methods need to be extended to be applicable on models of cyber-physical systems. Recent research [13,12,10] pursues this overall objective via the verification of models (of physical systems) with uncountable state spaces: of special interest is the safe-by-construction automatic synthesis of controllers. These correct-by-design controllers are however incompatible with general systems for which models with exact knowledge of the dynamics and full state measurements are not available.

Contributions

In this work we extend correct-by-design controllers for linear time invariant (LTI) models as in [13] to output-based controllers that employ sensor outputs or partial state measurements. As in [13], our new control architectures come with quantitative certificates on the accuracy. Further, since dynamics of physical systems are often disturbed in a probabilistic sense and associated sensors are noisy, we require the new output-based controllers to show quantifiable robustness with respect to stochastic disturbances on state evolutions and output measurements.

Related work

Design methods for classical optimal control problems [5] of models with (noisy) output measurements can be distinguished in direct designs based on the input-output behaviour of the system, and in methods exploiting the separation of estimation and control. The former class includes frequency-domain and robust control methods; alternatively, whenever applicable (as in the optimal linear quadratic Gaussian problem) the separation theorem [15] allows for the distinct design of an observer estimating the state and of a state feedback controller, yielding a combined output feedback controller.

Within the formal methods literature, limited efforts have targeted the synthesis of controllers for finite state models without state observations. Existing results target finite-state models: [7] studies the synthesis for partially observable models by searching the space of

For fully observable Markov Processes with general state spaces, verification and controller synthesis problems are reviewed in [1], and generally tackled over a simplified model that can be formally related to the original one. The simplified model can then shown to be in an (approximate) relation with the original model, either via metrics defined over the marginals of the conditional kernels [11], or via metrics bounding the distance between the output trajectories [9]. In contrast, this work will use the definition of approximate bisimulation relations, similar to those in [16], to quantify the expected deviation of noisy trajectories affected by stochastic disturbances.

Structure of the article

After reviewing preliminary notions in Sec. 2, the problem statement together with state-based, correct-by-design controller architectures [13,12] is given in Sec. 3. We design an output-based controller by introducing a state observer and a notion of output-based interface in Section 4. Under very standard controllability and observability conditions on the model, this design allows us to bound the deviation between state-based and output-based controllers (cf. Sec 5). Additionally Section 6 discusses robustness issues with respect to stochastic disturbances, both on state transitions and sensor measurements. Finally in Section 7 the design methodology is evaluated on a case study in the area of Smart Buildings.

2 Preliminaries

2.1 Transition systems and simulation relations

Definition 1 (Transition system [12]) A transition system is a tuple $\Sigma = (X, X_0, A, \rightarrow, Z, H)$, where

- $X$ is a (possibly infinite) set of states;
- $X_0$ is a (possibly infinite) set of initial states;
- $A$ is a (possibly infinite) set of actions;
- $\rightarrow \subseteq X \times A \times X$ is a transition relation;
- $Z$ is a (possibly infinite) set of observations;
- $H : X \rightarrow Z$ is a map assigning to each $x \in X$ an observation $H(x) \in Z$.

A metric transition system is a transition system endowed with a metric over the observation space $Z$.

This work considers non-blocking transition systems, where every state $x \in X$ is associated to a non empty transition relation. The behaviour generated by $\Sigma$ is denoted as $B(\Sigma)$ and consists of all infinite sequences $z_0, z_1, z_2, \ldots$ for which there exists an initialised path $(x_0, u_0), (x_1, u_1), (x_2, u_2), \ldots$, with $x_0 \in X_0$, $(x_i, u_i, x_{i+1}) \in \rightarrow$, and $z_i = H(x_i)$ for all $i \in \mathbb{N}$.

A transition system is called deterministic if the initial state is defined deterministically, i.e., $X_0 := \{x_0\}$, and for a given state-action pair the next state is determined uniquely.

The verification of LTI models can be attained by abstracting them as finite-state ones and leveraging symbolic approaches [12]. Pairs of models can be related as follows.

Definition 2 (Simulation relation [12]) Let $\Sigma_a = (X_a, X_0, A_a, \rightarrow_a, Z_a, H_a)$ and $\Sigma_b = (X_b, X_0, A_b, \rightarrow_b, Z_b, H_b)$ be transition systems with the same output sets $Z_a = Z_b$. A binary relation $R \subseteq X_a \times X_b$ is said to be a simulation relation from $\Sigma_a$ to $\Sigma_b$ if the following three conditions are satisfied:

1. for every $x_{a0} \in X_a$, there exists $x_{b0} \in X_b$ with $(x_{a0}, x_{b0}) \in R$;
2. for every $(x_a, x_b) \in R$ we have $H_a(x_a) = H_b(x_b)$;
3. for every $(x_a, x_b) \in R$ we have that $x_a \xrightarrow{a} x_{a}'$ in $\Sigma_a$ implies the existence of $x_b \xrightarrow{b} x_{b}'$ in $\Sigma_b$ satisfying $(x_{a'}, x_{b'}) \in R$.

We say that $\Sigma_a$ is simulated by $\Sigma_b$, or that $\Sigma_b$ simulates $\Sigma_a$, denoted as $\Sigma_a \preceq \Sigma \Sigma_b$, if there exists a simulation relation from $\Sigma_a$ to $\Sigma_b$. The transition systems $\Sigma_a$ and $\Sigma_b$ are simulation equivalent, $\Sigma_a \cong \Sigma \Sigma_b$ iff $\Sigma_a \preceq \Sigma \Sigma_b$ and $\Sigma_b \preceq \Sigma \Sigma_a$. The models $\Sigma_a$ and $\Sigma_b$ are bisimilar, i.e., $\Sigma_a \cong \Sigma \Sigma_b$, if there exists relation $R$ that is a simulation relation from $\Sigma_a$ to $\Sigma_b$ and for which $R^{-1}$ is also a simulation relation from $\Sigma_b$ to $\Sigma_a$.

Note that this similarity relation over the set of transition systems implies a relation over the behaviour of the transition systems [12], more precisely if $\Sigma_a \preceq \Sigma \Sigma_b$ then $B(\Sigma_a) \subseteq B(\Sigma_b)$, and if $\Sigma_a \cong \Sigma \Sigma_b$ then $B(\Sigma_a) = B(\Sigma_b)$.

Approximate versions of simulation relations allow for a more robust interpretation and can be considered over metric transition systems [12]. Consider two given metric transition systems with a shared output space $Z$ and a metric $d$ then an $\varepsilon$-approximate simulation relation The relation $R \subseteq X_a \times X_b$ is defined as follows (c.f. [12]).

Definition 3 (Approximate Simulation Relation) Let $\Sigma_a = (X_a, X_0, A_a, \rightarrow_a, Z_a, H_a)$ and $\Sigma_b = (X_b, X_0, A_b, \rightarrow_b, Z_b, H_b)$ be transition systems with the same output space $Z_a = Z_b$ with metric $d$. For $\varepsilon \in \mathbb{R}^+$, a relation $R \subseteq X_a \times X_b$ is said to be an $\varepsilon$-approximate simulation relation from $X_a$ to $X_b$ if the following three conditions are satisfied:

...
We say that \( \Sigma_a \) is approximately simulated by \( \Sigma_b \), or that \( \Sigma_a \) approximately simulates \( \Sigma_b \), denoted by \( \Sigma_a \preceq_\varepsilon \Sigma_b \), if there exists an \( \varepsilon \)-approximate simulation relation from \( \Sigma_a \) to \( \Sigma_b \). The models \( \Sigma_a \) and \( \Sigma_b \) are approximately bisimilar, i.e., \( \Sigma_a \sim_\varepsilon \Sigma_b \), if there exists a relation \( \mathcal{R} \) that is an \( \varepsilon \)-approximate simulation relation from \( \Sigma_a \) to \( \Sigma_b \) and for which \( \mathcal{R}^{-1} \) is an \( \varepsilon \)-approximate simulation relation from \( \Sigma_b \) to \( \Sigma_a \).

### 2.2 Formal specifications and control design

Let us consider a specification of interest \( \psi \) for which the desired behaviour is represented by a transition system \( \Sigma \) such that \( \mathcal{C} \times \Sigma \) satisfies the specification, namely (a.) if \( \mathcal{C} \times \Sigma \preceq_S \Sigma \psi \), or (b.) if \( \mathcal{C} \times \Sigma \sim_\varepsilon \Sigma \psi \). The notation \( \mathcal{C} \times \Sigma \) refers to the composition of the controller \( \mathcal{C} \) with model \( \Sigma \); the actions of the obtained transition system are defined by the controller \( \mathcal{C} \), whereas the internal state of \( \mathcal{C} \) is updated based on information available from \( \Sigma \).

If \( \Sigma_a \) and \( \Sigma_b \) are deterministic transition systems and \( \Sigma_a \preceq_S \Sigma_b \), then for every sequence of actions for \( \Sigma_a \), there exists a corresponding sequence for \( \Sigma_b \) such that the observed behaviour is the same [6]. Definition 2 suggests the refinement of a controller for \( \Sigma_a \) to \( \Sigma_b \) via condition 3): for every choice of \( u_a \), picked by the controller for \( \Sigma_a \), there exists a suitable input \( u_b \). In practice this allows synthesis problems to be first solved on a simplified, and possibly finite, abstraction \( (\Sigma_a) \), before refinement over a concrete, complex model \( (\Sigma_b) \).

### 3 Problem statement

We intend to synthesise a certifiable output-based controller for a physical system represented by the LTI model

\[
\begin{align*}
M &: \begin{cases}
x(t + 1) &= Ax(t) + Bu(t) \\
y(t) &= Cx(t) \\
z(t) &= Hx(t),
\end{cases}
\end{align*}
\]

(1)

where \( x(t) \in \mathbb{R}^n \) is the state, initialised by \( x(0) \in X_0 \subset \mathbb{R}^n \), the control input is \( u(t) \in \mathbb{R}^m \), and \( y(t) \in \mathbb{R}^p \) is the measured output available for control. \( A, B, C \) are real matrices of appropriate dimensions. The signals \( z(t) \in \mathbb{R}^q \), mapped from the state space via the linear map \( Hx \), are used to define performance and properties. This in unlike [17], which defines specifications over the signals \( y(t) \).

In contrast to the measured output \( y(t) \), the structure of which is physically specified by the sensors attached to the system, the choice of \( H \) can be adapted to the design requirements, and include \( H = C \) and \( H = I \) as special cases.

The LTI model \( M \) can be reinterpreted as a transition system characterised by a tuple \((\mathbb{R}^n, X_0, \mathbb{R}^m, \to, \mathbb{R}^n, H)\), with a state space \( x \in \mathbb{R}^n \), a set of initial states \( x(0) \in X_0 \), and transitions \( \to := \{ x, u, x' | x' = Ax + Bu \} \). Additionally, \( H \) assigns observation \( z \in \mathbb{R}^q \) to \( x \in \mathbb{R}^n \); \( z = Hx \). Note that this transition system has uniquely defined transitions, since for every state-action pair there is a unique state transition.

#### 3.1 State-of-the-art correct-by-design controller synthesis

Suppose that an LTI model \( x(t + 1) = Ax(t) + Bu(t) \) is given, and that it has a finite-valued observation map that induces a partition over the observation space \( \mathbb{R}^q \). Under assumptions on the controllability of the model, on the linear independence of the columns of its input matrix \( B \), and on the observation map [13, 12], the LTI model can be bisimulated by a finite transition system. Alternatively, under less stringent conditions it is possible to synthesise a finite approximate bisimulation of the given model [12, 10]: further, for every controller synthesised on the finite-state abstraction there exists a refined controller for the original model, with the same closed-loop behaviour.

In the remainder of this work we assume that given a model \( M \) and a model \( \Sigma_{\psi} \) for the specification, both with the same output space, we have obtained a controlled model \( M_{\mathcal{C}} \), which is such that \( M_{\mathcal{C}} \sim_S \Sigma_{\psi} \). \( M_{\mathcal{C}} := C \times M \) denotes the composition of model \( M \) with the correct-by-design controller \( \mathcal{C} \), where \( C \) takes as input the state of \( M \) and returns an action to \( M \). This controlled model has hybrid states \((\bar{x}, q) \) with \( \bar{x} \in \mathbb{R}^n \) and \( q \in Q \), where \( Q \) is a finite set. Its dynamics are defined as

\[
M_{\mathcal{C}} : \begin{align*}
\bar{x}(t + 1) &= Ax(t) + B\bar{u}_q(\bar{x}(t)) \\
q(t + 1) &= \delta(\bar{x}(t), q(t)),
\end{align*}
\]

(2)

and initialised by \((\bar{x}(0), q(0)) \in \bigcup_{q_0 \in Q_0 \subset \{q_0 \} \times \bar{X}_0(q)) \). Let us remark that the discrete states of this model follow from the states of a finite transition system, approximately bisimilar to the continuous-state model \( M \), and from the discrete states of the specification model \( \Sigma_{\psi} \). Hence the discrete state \( q \) is initialised based on the specification model \( \Sigma_{\psi} \) and the initial state \( \bar{x}(0) \). Note that
Suppose that there exists a state-based, correct-by-
design controller for a fully-observed LTI model, with
closed-loop dynamics denoted by $M_C$ as in (2). The
objective of this work is to design an output-based
controller, a controller that only requires the measured
signal $y(t)$ and that can therefore be deployed on the
model in (1). Additionally, it is required that the new
controller guarantees an upper-bound on the deviation
from the state-based control in (2).

In the following we use the notion of interface function.
Interface functions originate from the work in [6] on hi-
erarchical control design based on (approximate) sim-
ulation relations: the construction of a controller over
a simplified model is refined to a concrete model while
maintaining the same guarantees over the controlled
behaviour.

**Definition 4 (Interface function)**

Let $\Sigma_a = (X_a, X_{a0}, A_a, \to_a, Z_a, H_a)$ and
$\Sigma_b = (X_b, X_{b0}, A_b, \to_b, Z_b, H_b)$ be deterministic transition systems with the same output sets $Z_a = Z_b$. A relation $R \subset X_a \times X_b$ is an $\varepsilon$-approximate simulation relation from $X_a$ to $X_b$, and $F : A_a \times X_a \times X_b \to A_b$ is its related interface, if the following three conditions are satisfied: (1) for every $x_{a0} \in X_{a0}$, there exists $x_{b0} \in X_{b0}$ with $(x_{a0}, x_{b0}) \in R$; (2) for every $(x_a, x_b) \in R$, $d(H_a(x_a) - H_b(x_b)) \leq \varepsilon$; (3) for every $(x_a, x_b) \in R$ we have that $x_a \xrightarrow{u_{a0}} x_a'$ in $\Sigma_a$ implies $x_b \xrightarrow{u_{b0}} x_b'$ in $\Sigma_b$ with $u_0 = F(u_a, x_a, x_b)$, satisfying $(x_a', x_b') \in R$. The feedback composition of $\Sigma_a$ and $\Sigma_b$ is denoted as $\Sigma_a \times_f \Sigma_b$. $\square$

Note that the existence of an (approximate) simulation relation implies the existence of an interface, i.e., for all $\varepsilon$-approximately simulated and deterministic transition systems there exists at least one interface function.

In practice Definition 4 entails that the dynamics corresponding to the feedback-composed models $\Sigma_a \times_f \Sigma_b$ do not differ more than $\varepsilon$. Hence, a controller composed on $\Sigma_a$ can be refined to $\Sigma_b$ via the interface $F$, without affecting its closed-loop accuracy more than $\varepsilon$.

Let us define a specific class of interfaces denoted as sensor-based interfaces, which are defined exclusively based on sensor information from $\Sigma_b$, namely $F_g : A_a \times X_a \times g(X_b) \to A_b$, where $g$ is the sensor function. In the particular instance of (1), the sensor function is $g(x(t)) := Cx(t)$. These structures are of interest to us, as they define the set of interfaces that can be practically implemented for controller refinement on partially observable systems.

$u_q(x(t))$ is a function that maps the current state to an action.

### 3.2 Problem statement

Consider a Luenberger observer denoted as $O$:

$$
\dot{x}(t + 1) = A\hat{x}(t) + Bu(t) + L(y(t) - \hat{y}(t)) , \\
\hat{y}(t) = C\hat{x}(t),
$$

with gain matrix $L$ such that $A - LC$ is stable if $(A, C)$ is detectable [5]. The observer is initialised as $\hat{x}(0)$, and uses the outputs from $M$ to estimate its internal state. The composition of $M$ with its observer $O(M)$ is denoted as $M||O(M)$ and portrayed in Fig. 1.

Denote the sensor-based interface as

$$
\mathcal{F}_g(\bar{u}, \bar{x}, \bar{x}) = \bar{u} + K(\bar{x} - \hat{x}),
$$

where $\bar{u}$ is the action selected by $M_C$ (this role is played by $\bar{u}_0$ in (2)). For this linear interface we demand that matrix $A - BK$ is stable. Note that the interface is sensor-based (as defined in Section 2), since the state estimate $\hat{x}$ of $x$ can be obtained from the sensor function of $M||O(M)$, thus $g(x, \hat{x}) = \hat{x}$.

The overall controlled model $M_C \times F_g (M||O(M))$, denoted as $M_C$, is the result of interfacing the two structures discussed above, as depicted in Fig. 2. This has dynamics evolving over the continuous state space $\mathbb{R}^m$ as:

$$
\dot{x}(t + 1) = A\hat{x}(t) + B\bar{u}_q(\bar{x}(t)) \\
\dot{\bar{x}}(t + 1) = (A - LC)\hat{x}(t) + Bu(t) + LCx(t) \\
x(t + 1) = Ax(t) + Bu(t) \\
\bar{u}(t) = \mathcal{F}_g(\bar{u}_q(\bar{x}(t)), \bar{x}(t), \dot{\bar{x}}(t))
$$

in combination with the discrete transitions $q(t + 1) = \delta(\bar{x}(t), q(t))$ from (2).
Remark 1 As depicted in Fig. 2, we have designed an output-based controller by combining a given state-based controller with an observer. However, unlike classical results where a state-based controller is employed over estimated states from an observer, in this work we have interfacen the state-based controlled model $M_C$ with the model/observer interconnection $M|O(M)$, as in Fig. 1. This allows one to reason explicitly about the accuracy of the overall output-controlled system, based on the accuracy of the sensor-based interface function. In special cases the proposed architecture can reduce to the classical approach. □

\[
\begin{align*}
\mathcal{R} := \left\{ (q, \tilde{x}, \hat{x}, x) \mid \left[ \begin{array}{c} z(t) - \tilde{z}(t) \\ H(t) \end{array} \right] \leq \left[ \begin{array}{c} H \end{array} \right] \right\}
\end{align*}
\]
and (4) are a simulation relation and interface function for the models $M_C$ and $M|O(M)$, since all three conditions are satisfied. The first follows immediately from (7). The second can be shown as follows $z(t) - \tilde{z}(t) = H(\hat{x}(t) - \bar{x}(t)) + H(x(t) - \bar{x}(t))$

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5]. Note that since both $\bar{x}(0)$ and $\tilde{x}(0)$ are included in the design space, it would not make much sense to select $\bar{x}(0) \neq \tilde{x}(0)$ for the initialisation. Hence, the accuracy depends on the initial states of the models only via $x(0) - \tilde{x}(0)$. In case the initial state $x(0)$ is only known up to a set $X_0$, the guarantee in Theorem 5 is required to hold over all $x(0) \in X_0$. The proof of the theorem is given as follows.

\[
\begin{align*}
\varepsilon := \sqrt{\text{trace} \left( [H H] \right)}
\end{align*}
\]

Proof The relation

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]

Thus the distance between $\tilde{z}(t)$ and $z(t)$ is bounded by $\varepsilon$ if there exists a $Q$ for which (7) and (8) are satisfied. A stability assumption on matrices $A - BK$ and $A - LC$ guarantees this [5].

\[
\begin{align*}
\frac{z(t) - \tilde{z}(t)}{Q} \leq \left[ \begin{array}{c} \hat{x}(t) - \bar{x}(t) \\ A - BK & LC \end{array} \right] \left[ \begin{array}{c} A - BK \\ A - LC \end{array} \right] \frac{z(t) - \tilde{z}(t)}{Q} \leq 0
\end{align*}
\]
A. Let $\bar{M}$ be a noiseless version of $M$ in (9), and $M_C$ be the composition of $M$ with its correct-by-design controller;
B. Design a state observer $O(M)$ for $M$;
C. Design a linear interface function $F_q$ stabilising $A - BK$;
D. Implement the control structure in Fig. 2, and denote the resulting controlled stochastic model as $M_C := M_C \times F_q(M \| O(M))$.

The initial conditions for $M_C$, namely $\bar{x}(0), \bar{\dot{x}}(0)$, are selected as part of the control design problem: as discussed earlier, we pick $\bar{x}(0) = \bar{\dot{x}}(0)$. Further, let $q(0)$ be any discrete state such that $(\bar{x}(0), q(0)) \in \bigcup_{x_0 \in Q_0} \{(x_0 \times X_0(q)\}$.

In order to analyse the behaviour of the controlled stochastic model $M_C$ with respect to a metric of interest, let us embed $M_C$ into the formalism of deterministic transition systems (cf. Definition 1) as in [16]. The model can be represented as a symbolic transition system $\Sigma^*(M_C)$, with states encompassing random variables $x_C(t)$ representing the distribution of $x(t) \sim x_C(t)$, with $x_C(t) \in \mathbb{R}^n$ as in (5). Consider the metric output space $Z$, to which the states are mapped as $z_C(t) = H x_C(t)$. Further consider the metric $d^*(z_1 - z_2) = \mathbb{E}(\|z_1 - z_2\|_2)$, with $\| \cdot \|_2$ the Euclidean norm. Denote the set of all transition systems with the metric output space $Z$ as $T^*$.

Both the specification model $\Sigma_\psi$ and the correct-by-design controlled model $M_C$ can be trivially embedded in $T^*$ via singleton distributions: we denote the corresponding symbolic transition systems as $\Sigma^*_\psi$ and $\Sigma^*(M_C)$, respectively. We obtain:

**Theorem 6** Transition system $\Sigma^*(M_C)$ is approximately bisimulated by $\Sigma^*_\psi(M_C)$ with precision $\epsilon$ obtained as

$$\epsilon := \sqrt{\text{trace}(\begin{bmatrix} H & H \end{bmatrix} Q [H H]^T)} \quad (10)$$

where

$$\begin{bmatrix} A - BK & LC \\ 0 & A - LC \end{bmatrix} Q \begin{bmatrix} A - BK & LC \\ 0 & A - LC \end{bmatrix}^T + \begin{bmatrix} L E E_1^T L_1^T & - L E E_1^T L_1^T \\ - L E E_1^T L_1^T & F F_3 + L E E_1^T L_1^T \end{bmatrix} - Q \preceq 0. \quad (12)$$

As a consequence of Theorem 6 it follows that if $\Sigma^*_\psi(M_C) \preceq_{S^*} \Sigma^*_\psi$, then $\Sigma^*(M_C) \preceq_{S^*} \Sigma^*_\psi$, and if $\Sigma^*(M_C) \sim_{B^*} \Sigma^*_\psi$, then $\Sigma^*(M_C) \sim_{B^*} \Sigma^*_\psi$. Finally note that (12) is known to admit positive matrices $Q$ for which $\epsilon$ is finite if $A - BK$ and $A - LC$ are both stable matrices [5].

**Proof** The composition of $M_C$ with $M \| O(M)$ over the interface (4) gives the continuous dynamics of as $\Sigma^*(M_C)$

$$\dot{x}(t + 1) = A \bar{x}(t) + B \bar{u}(\bar{x}(t))$$

$$\dot{x}(t + 1) = (A - LC) \bar{x}(t) + B u(t) + LC x(t) + LE \bar{w}(t)$$

$$x(t + 1) = A x(t) + B u(t) + F \bar{w}(t)$$

$$u(t) = u_q(\bar{x}(t)) + K(\bar{x}(t) - x(t))$$

Note that we have trivially assumed that this (bi-) simulation relation between the transition system $\Sigma(M_C)$ and $\Sigma_\psi$ is maintained when embedding them in $T^*$ via Dirac distributions [16].
with output $z(t) = Hx(t)$. Consider the relation $\mathcal{R}$ defined as

$$\mathcal{R} := \{(q', \tilde{x}'), (q, \tilde{x}, x, x) \mid \tilde{x}' = \tilde{x}, q' = q, \quad \Delta \mathbb{E} \left[ \left( ([\tilde{x} - \tilde{x}]^T (x - \tilde{x}))^T ([\tilde{x} - \tilde{x}]^T (x - \tilde{x})) \right)^T \right] \leq Q \}$$

where $\tilde{x}'$ is the continuous state of $\Sigma^*(\mathcal{M}_C)$ and $x_C := [\tilde{x}^T \tilde{x}^T x^T]$, the continuous state of $\Sigma^*(\mathcal{M}_C)$. The outputs $z'$ and $z$ are similarly defined. For future reference note that applying the congruence transform with the first condition holds. Secondly for all $(\tilde{x})$ $R$ $z$ $\tilde{x}$ is defined as $q := \tilde{x}, q' = q, \quad \Delta \mathbb{E} \left[ \left( ([\tilde{x} - \tilde{x}]^T (x - \tilde{x}))^T ([\tilde{x} - \tilde{x}]^T (x - \tilde{x})) \right)^T \right] \leq Q$

$$\tilde{x}(t + 1) = A\tilde{x}(t) + B\tilde{u}_p(\tilde{x}(t))$$

$$\Delta x(t + 1) = (A - BK)\Delta x(t) + LCE(t) + LEw(t)$$

$$e(t + 1) = (A - LC)e(t) + (F - LE)w(t)$$

$$\tau(t) = H\tilde{x}(t) + H\Delta x(t) + He(t).$$

Firstly condition 1) for an approximate bisimulation holds: $\tilde{x}(0) = x(0), \tilde{x}(0) - x(0) = 0$ and $\mathbb{E} \left[ (x(0) - \tilde{x}(0))^T (x(0) - \tilde{x}(0)) \right] = (x(0) - \tilde{x}(0))^T(x(0) - \tilde{x}(0)) + P_0$. Therefore based on (11) it follows that the first condition holds. Secondly for all $((q', \tilde{x}'), (q, \tilde{x}, x, x)) \in \mathcal{R}$: the metric $\mathbb{E} [||z' - z||^2]$ can be written as

$$\mathbb{E} [||H\tilde{x}' - Hx||^2_2] \leq \sqrt{\mathbb{E} [(H\tilde{x}' - Hx)^T (H\tilde{x}' - Hx)]}$$

$$\leq \sqrt{\text{trace} \mathbb{E} [H(X' - X)(X' - X)^TH^T]}.$$
controllers, consider a building that is divided into two connected zones, each with a radiator regulating the heat in each zone via the controlled boiler water temperature \[8\]. Due to a sensor fault in the second zone, only the temperature in the first zone and the ambient (outside) temperatures are measured. The temperature fluctuations in the two zones and the ambient temperature are modelled via \(M\) as \[8\]

\[
x(t + 1) = \Xi x(t) + \Gamma u(t) + Fw_1(t) \\
y(t) = [1 0 0 1]x(t) + Ew_2(t), \quad z(t) = [1 0 1 0]x(t),
\]

with stable dynamics

\[
\Xi = \begin{bmatrix} 0.8725 & 0.0625 & 0.0375 \\ 0.0625 & 0.8775 & 0.0250 \\ 0 & 0 & 0.9900 \end{bmatrix}, \quad \Gamma = \begin{bmatrix} 0.0650 & 0 \\ 0 & 0.0600 \end{bmatrix},
\]

where \(x_{1,2}(t)\) are the temperatures in zone 1 and 2, respectively; \(x_3(t)\) is the deviation of the ambient temperature from its mean; and \(u(t) \in \mathbb{R}^2\) is the control input. Note that since \(\Xi\) is stable, it follows that \((\Xi, \Gamma)\) is stabilisable and \((\Xi, [1 0 0])\) is detectable. The state variables are initiated as \(x(0) = [16 14 -5]^{T}\). The constants in matrix \(\Xi\) are selected to represent the heat exchange rate between the individual zones and the heat loss rate of each zone to the ambient; those in \(\Gamma\) represent the rate of heat supplied by the radiators to the two zones, respectively. The disturbances are modelled as independent and identically distributed standard normal distributions \(w_{1,2}(t)\), rescaled by

\[
F = \begin{bmatrix} 0.05 & -0.02 & 0 \\ -0.02 & 0.05 & 0 \\ 0 & 0 & 0.01 \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} 0.05 & 0 \\ 0 & 0.05 \end{bmatrix}.
\]

The upper block in \(F\) represents random heat transfers, caused for example by people moving within and between zones, whereas the lower, right-diagonal element represents the stochastic nature of the fluctuation in the outside temperature. The values in \(E\) define the standard deviation of the additive disturbance on the temperature sensors in the first zone and in the ambient. \(y(t)\) is the stochastic signal that can be measured, whereas the specification is defined over \(z(t)\) (zone temperatures).

The objective is to design an output-based, correct-by-design controller, such that the temperature trajectories \(z(t) = (x_1(t), x_2(t))\) eventually both take values in the interval \([20.5, 21]^2\), and remain within this interval thereafter. The controller is initialised with \(\hat{x}(0) = [16 16 0]^{T}\); this deviation from \(x(0)\) is selected to model a realistic situation occurring after a sensor failure in zone 2 is discovered.

The dynamics of the noiseless model \(\hat{M}\) are solely governed over the first two states, where the correct-by-design controller for the given specification is designed.

### Table 1

| Error Bounds - Accuracy of the controlled systems based on the interface. An initialisation is given by \(\bar{x}_{e,0}\) for the perfect initialisation, or for \(t \to \infty\) the system the accuracy is given as \(\varepsilon_{\infty}\). The estimates \(\hat{x}_{e,100}\) and \(\varepsilon_{\infty}\) are computed as \(\sqrt{\varepsilon_{e,100}}\) and \(\sqrt{\varepsilon_{e,0}}\) respectively, with the empirical mean computed as \(R_x = \frac{1}{t - 1} \sum_{k=1}^{t-1} x(k)\). |
|-----------------|-----------------|-----------------|-----------------|
| \(M_{C} \times F_{\bar{f}}\) \(M\) | \(\varepsilon_{\infty}\) | \(\varepsilon_{e,0,100}\) | \(\hat{x}_{e,100}\) |
| \(M_{C} \times F_{\bar{f}}\) \(M\) | 3.9618 | 0.4890 | 1.9961 | 0.4845 |
| \(M_{C}\) | 2.1194 | 0.1284 | 0.5184 | 0.1240 |

We synthesise \(M_{C}\) by PESSOA \[10\], where the discrete-time dynamics are further discretised over state and action spaces: we have selected a state quantisation of \(0.05\) over the range \([15, 25]^2\), and an input quantisation of \(0.05\) over \([10, 30]^2\). Fig. 3a displays (continuous blue line) the state trajectory of the obtained correct-by-design system \(M_{C}\); it can be observed that the controller regulates the model to eventually remain within the target region.

Next, we are interested in extending the designed controller to the concrete (noisy) model of the system based on noisy output measurements of the first zone and of the ambient. As a first attempt we implement the controller based on a feedforward architecture, where \(F_{\bar{f}} = \hat{u}(t)\). This is what we would obtain applying the results in \[16\]. It can be observed in Fig. 3a (circled red realisation) that a trajectory \((x_1(t), x_2(t))\) in \(M_{C} \times F_{\bar{f}}\) \(M\) deviates substantially from the desired temperature range. In Table 1 the accuracy of this feedforward interface is given. As a second design, we implement the structure in Fig. 2, where the gains \(K, L\), as detailed in Subsection 6.1, are selected as the optimal LQ and Kalman gains, respectively. The resulting design values are

\[
L = \begin{bmatrix} 0.5201 & 0.0333 \\ -0.2239 & 0.0262 \end{bmatrix} \quad \text{and} \quad K = \begin{bmatrix} 13.4231 & 0.9615 & 0.5769 \\ 1.0417 & 14.6250 & 0.4167 \end{bmatrix}.
\]

A trajectory (crossed grey line in Fig. 3a) realised from \(M_{C} = M_{C} \times F_{\bar{f}}\) \((M|O(M))\) and based on the previous noise realisation ends up close to the desired temperature range. This substantial improvement with respect to the feedforward interface is also quantified in Table 1. Fig. 3b displays the error of the state estimation \(\hat{x}(t) - \hat{x}(t)\) of \(M_{C}\) (upper plot); it can be observed that the estimated state converges to the exact state. The lower plot in Fig. 3b provides a simulation of the deviation of the ambient temperature from its mean.

### 8 Conclusions and future work

In this work we have shown that correct-by-design controllers can be extended to work on stochastic partially-observable LTI systems, as long as the LTI system is detectable and stabilisable. Future work will concern extensions to non-linear dynamics and the development of tailored notions of probabilistic approximations.
