The phenomenon of the (A,B,C) triplet of infrared OH bands at ~2800, ~2400 and ~1700 cm⁻¹, well-known for strong X—OH=Y molecular H-complexes in solutions, liquids, and solids, is studied for the first time for surface H-complexes using CD₃CN and CC₁₂CN adsorption on deuterated H-ZSM₅ and H-FeSil zeolites. A direct experimental proof is given that the minimum between the A and B bands of D-complexes occurs at nearly exactly the 2Δ(OD) in-plane bending overtone frequency of the perturbed OD group. This verifies the resonance theory of the (A,B) doublet by Claydon and Sheppard. In reference to zeolites this means that the ~2800 and ~2400 cm⁻¹ OH bands recently found in adsorption of many basic molecules on zeolitic OH groups are actually pseudobands, caused by the subdivision of the very broad ν(OH) ± kv(OH=Y) superposition band of the perturbed OH groups by Evans transmission window at the 2Δ(OD) ~ 2600 cm⁻¹ frequency.

Introduction

In our recent IR and ab initio studies of the ~2800, ~2400 and ~1700 cm⁻¹ infrared OH bands found in adsorption of many basic molecules on zeolitic Bronsted sites were supposed to be analogous with the so-called (A,B,C) triplet of OH bands of strong molecular H-complexes in solutions, liquids, and solids. Although the (A,B,C) triplet has been quite well explored for these media more than 20 years ago, the corresponding ideas have not gained currency in the interpretation of the similar phenomenon for surfaces. Some examples of H-complexes producing these three OH bands in solutions, solids, and zeolites are collected in Table 1.

Three different theories have been proposed to explain the origin of the (A,B,C) triplet. According to the resonance theory by Claydon and Sheppard, the A, B, and C bands of X—OH=Y complexes are actually pseudobands, caused by the subdivision of the very broad OH stretching band of the perturbed OH group by two Evans transmission windows at ~2600 and ~1900 cm⁻¹. As Evans and Wright showed, when a sharp IR band overlaps a broad fundamental band of the same symmetry, this can lead to a “transmission window” in the broad band at the frequency of the sharp band. Evans gave also a theoretical interpretation of this phenomenon, the “missing” intensity being redistributed to both sides of the window by Fermi resonance repulsion between the vibrational levels of the superimposed bands. In the theory by Claydon and Sheppard the transmission windows were supposed to be due to Fermi resonance of the ν(OH) ± kv(OH=Y) combination modes, producing the broad OH band according to the frequency modulation theory of the ~2600 cm⁻¹ in-plane and 2ν(OH) ~ 1900 cm⁻¹ out-of-plane bending overtones of the perturbed OH group (ν(OH=Y) designates the intermolecular stretching frequency). Later this hypothesis was further theoretically developed by Bratos and Ratajczak by applying the standard techniques of nonequilibrium statistical mechanics. A semiempirical model mainly based on this theory reproduced very well the (A,B,C) structure of experimental IR spectra of CSHSeO₄ crystals.

C bands of X-OH=Y complexes to be individual IR bands corresponding to the 2δ(OH), v(OH), and 2γ(OH) frequencies, respectively, with the A and C bands being strongly enhanced and shifted by the 2δ(OH) ↔ v(OH) ↔ 2γ(OH) resonance interactions with respect to the unperturbed 2δ(OH) and 2γ(OH) frequencies.25,26 In this interpretation two "holes" between the A, B, and C bands are not taken to be Evans windows. A semimpirical model developed by Odinokov et al.25,26 was successfully applied for predicting the C band maximum and the A + B band "center of gravity" wavenumbers for a wide range of H-complexes of benzoic, acetic, monocarboxylic, and triacetic acids. As to the application of this theory to surfaces, it was used by Angelli and Howell3 to explain an unexpected experimental result that acetoniitrile complex with the structural OH group of HY zeolite, which should have only one OH stretching mode, generates two OH bands at 2800 and 2400 cm⁻¹.

The third theory, the double-minimum theory,19,32–35 postulates that the (A,B,C) infrared structure of strong H-complexes is produced by a pair of quasi-generate vibrational levels of an asymmetric double-minimum proton potential, corresponding to the "neutral" X–OH–Y and "ionic" X–O–Y+ states of these complexes. Considering the proton tunneling through the potential barrier between two minima, the selection rules for transitions amongst the lowest levels in such a potential permit four of the infrared active modes. As the separation between the corresponding OH bands and their intensity depend on the exact shape of the potential, only three or fewer bands may be found under certain circumstances. So far, no quantitative agreement has been obtained between spectral characteristics of an observed (A,B,C) triplet and the results of their calculations using a suitable double-minimum potential. As Hadzi noticed,19 the chances of such agreement are very small. It is necessary either to have a very good model to start from or to carry out an immense number of calculations in view of the large number of physically possible double-minimum situations and the lack of initial data. Nevertheless, this model of strong H bonding is in wide use now. In an experimental study by Kubelkova et al.4 it was utilized for the interpretation of IR spectra of acetone, diethyl ketone, and mesityl ketone adsorption on Bronsted sites of H-ZSM5 zeolite: the ~2800 and ~2400 cm⁻¹ bands were associated with the "neutral" and "ionic" states of the adsorption H-complexes. Also, in an IR study by Parker et al.5 these OH bands found in adsorption of many other basic sorbants on H-ZSM5 were explained in terms of the double-minimum model.

In our recent studies1,2 the ~2800, ~2400, and ~1700 cm⁻¹ OH bands of zeolitic H-complexes were supposed to conform to the resonance theory by Claydon and Sheppard. The main change in the interpretation of IR spectra of surface H-complexes, caused by the extension of this theory to surfaces, results from the fact that the ~2800, ~2400, and ~1700 cm⁻¹ bands should be associated not with three different OH modes of these complexes, as generally accepted in the literature now,3–18 but with the v(OH) mode of the perturbed OH group only. For example, in previous experimental IR studies5,10,12,14,17,18 of water and methanol complexes with the zeolitic OH group the 2900, 2450, and 1700 cm⁻¹ bands were assigned to the antisymmetric, symmetric, and deformation OH vibrations of H₂O and CH₃OH⁺ ions, respectively. As shown in ref 2, the resonance theory suggests a substantially new assignment of OH bands for these complexes and leads to the conclusion that they are "neutral." Considering numerous IR studies devoted to surface H-complexes during the last 50 years, a modern reconsideration of their IR data on the basis of the resonance theory can lead to a significant revision of many other previously accepted interpretations. To justify such utilization of the resonance theory, its experimental proof becomes very topical, in view of the fact that at present this theory can be regarded as only a fairly reasonable one, for it has not been rigorously proved for a concrete case of the (A,B,C) triplet. As follows from above, this has a direct bearing also on discriminating between the single-minimum model of strong H bonding, tacitly assumed by the resonance theory, and the double-minimum model. Also an experimental validation of the analogy between the (A,B,C) triplet of molecular H-complexes and the ~2800, ~2400, and ~1700 cm⁻¹ OH bands of surface H-complexes is very important, considering that the phenomenon of the (A,B,C) triplet has never been specially studied for surface H-complexes.

Here the (A,B,C) triplet is investigated for surface H-complexes using CD₃CN and CCl₃CN adsorptions on deuterated H-ZSM5 and H-FeSiSil zeolites. A direct experimental proof will be given for the first time in the study of this phenomenon that the wavenumber of the minimum between the A and B bands of D-complexes is nearly equal to the 2δ(OD) overtone frequency of the perturbed OD group. This verifies the hypotheses by Claydon and Sheppard about the nature of the A and B bands.

Experimental Section

Zeolites. ZSM-5 was synthesized hydrothermally at 443 K for 48 h with TPABr as a templating agent. A Si/Al = 52 ratio for this zeolite was estimated on the basis of adsorption calorimetric measurements, taking an amount of the adsorbed ammonia at 423 K as a measure of the SiOAH₅ lattice sites.34

MFI ferriolsilicate FeSiSil was prepared using iron sulfate and silicate solution as described in detail in ref 37. A Si/Fe = 32 ratio was determined by adsorption calorimetric measurements (see above).

Deuteration was performed by reacting the activated samples for 1.5 h at 623 K with 100 mbar of D₂.

IR Measurements. IR spectra were recorded at room temperature using a Bruker 113v FTIR spectrometer with a heatable vacuum cell. The samples were pressed into 7.5 mg/cm² disks. Before gas dosage the samples were activated for 1 h at 723 K under 10⁻¹⁰ mbar pressure.

Results and Discussion

In agreement with recent experimental studies by Jacobs et al.38,39 H → D exchange of H-ZSM5 and H-FeSiSil zeolites gives rise to the 3δ(OD) bands of the bridging SiODAl and SiODFe groups at 894 and 865 cm⁻¹, respectively, between the very intense bands of symmetric (600–800 cm⁻¹) and antisymmetric (1000–1300 cm⁻¹) lattice stretching vibrations40,41 of these zeolites. Figure 1 and Table 2 show the changes of these bands caused by the CD₃CN and CCl₃CN adsorptions. According to our IR and ab initio studies of CD₃CN interaction with zeolitic OH groups,1 these adsorptions should result in the formation of four different medium-strong D-complexes.

replacements, CD\textsubscript{3}CN being more basic compared with CCl\textsubscript{3}-CN and SiODAl being more acidic compared with SiODFe.\textsuperscript{37}

replacing SiODFe with SiODAl (by \(-10\text{ cm}^{-1}\)) in structure

due to the strengthening of the acid-base interaction by these

| TABLE 2: \(\delta(OD)\) Band and Transmission Window Minimum Wavenumbers (cm\textsuperscript{-1}) |
|---------------------------------|-------|-------|-------|-------|
| Bronsted site                  | \(\delta(OD)\) | \(\delta(OD)\) | \(\Delta\delta(OD)\) | Window |
|                                | CCl\textsubscript{3}CN adsorption | CD\textsubscript{3}CN adsorption | |
| SiODAl                         | 894 | 988 | 94 | 1977 (1976)* | 970 | 76 |
| SiODFe                         | 865 | 950 | 85 | 1902 (1900)* | 930 | 65 |

* Twice the \(\delta(OH)\) frequency of the perturbed OH group.

Both the small \(\Delta\delta(OD)\) = \(65-95\text{ cm}^{-1}\) upward frequency shift and the insignificant change of the \(\delta(OD)\) band intensity in these interactions (Figure 1 and Table 2) are in good agreement with previous experimental studies of the OH\textsuperscript{(0D)} bending mode for molecular H(D)-complexes.\textsuperscript{42}

The \(\Delta\delta(OD)\) shift increases upon replacing CCl\textsubscript{3}CN with CD\textsubscript{3}CN (by \(-20\text{ cm}^{-1}\)) and upon replacing SiODFe with SiODAl (by \(-10\text{ cm}^{-1}\)) in structure 1 due to the strengthening of the acid-base interaction by these replacements, CD\textsubscript{3}CN being more basic compared with CCl\textsubscript{3}CN and SiODAl being more acidic compared with SiODFe.\textsuperscript{37} This also agrees with IR studies of the OH\textsuperscript{(0D)} bending mode for molecular H(D)-complexes.\textsuperscript{42}

It is to be noted that in previous experimental studies of the (A,B,C) triplet, performed mainly for H-complexes of organic acids in solutions and liquids, the \(\delta(OD)\) band fell into the heavily populated "fingerprint" spectral region of these compounds at 500-1500 cm\textsuperscript{-1}.\textsuperscript{19,20,42} The identification of the \(\delta(OD)\) band is known to be very difficult in this case.\textsuperscript{9}

In an experimental study by Claydon and Sheppard\textsuperscript{20} H \(\leftrightarrow\) D exchange combined with low-temperature IR techniques was used in order to locate accurately the \(\delta(OH)\) fundamental for H-complexes of liquid phenylphosphonic and dibutylarsinic acids. As a result of this investigation, the conclusion was made that the \(2\delta(OH)\) frequency of these two complexes corresponds approximately not with the A band maximum, as one could expect according to a previously proposed\textsuperscript{19,24} interpretation of the (A,B,C) triplet, but with the minimum between the A and B bands. However, the found difference between the minimum wavenumber and the \(2\delta(OH)\) frequency (\(-100\text{ cm}^{-1}\) for dibutylarsinic acid) was too large for this result to be regarded as an experimental proof of the resonance theory.\textsuperscript{20}

Therefore, an alternative theoretical interpretation was suggested later\textsuperscript{25,26} for the (A,B,C) infrared structure by Odinokov et al. (see the Introduction). In the present study an attempt is undertaken to prove the resonance theory of the (A,B) doublet by comparing the \(2\times\delta(OD)\) frequency with the wavenumber of the minimum between the A and B OD bands for the above-mentioned zeolitic D-complexes. According to refs 20, 25, and 26, this transmission window should be significantly narrower for D-complexes as compared with H-complexes. This is accounted for\textsuperscript{20} by a strong weakening of the Fermi coupling between the stretching fundamental and the bending overtone due to the anharmonicity decrease by H \(\leftrightarrow\) D exchange.\textsuperscript{25,26} As follows from theoretical constructions of the window for cases of a comparatively weak Fermi resonance,\textsuperscript{21} we can expect the wavenumber of the minimum between the A and B OD bands to be equal to the \(2\times\delta(OD)\) frequency within a few cm\textsuperscript{-1} if the resonance theory is correct. Assuming \(2\delta(OD) = 2\times\delta(OD)\), the anharmonicity of the \(\delta(OD)\) vibration is thus neglected. This is not believed to be a serious error, as the \(X_{64}\) anharmonicity constant of \(\delta(\text{XH})\) bending modes is known to be very small\textsuperscript{25} (see also below). As an example, the wavenumber of a narrow Evans window in the OD stretching band of OD\textsubscript{2} complexes with Na\textsuperscript{+} and Ag\textsuperscript{+} cations in Na\textsubscript{2}Ag\textsubscript{3}A zeolites (the OD groups are nonbonded in this case) was found by Baumann et al.\textsuperscript{43} to be equal to the \(2\times\delta(OD)\) frequency to an accuracy of a few cm\textsuperscript{-1}.

Figure 2 shows the changes in the 1300-4000 cm\textsuperscript{-1} spectral region for CD\textsubscript{3}CN and CCl\textsubscript{3}CN adsorptions on H-ZSM5, H-FeSil, H/D-ZSM5, and H/D-FeSil zeolites. Two broad OH bands appear at \(\sim 2800\) and \(\sim 2400\text{ cm}^{-1}\) in the adsorptions on the H-zeolites, typical for medium-strong X-OH-Y molecular complexes in solutions, liquids, and solids.\textsuperscript{19,20,25,26} The so-called A and B bands. For molecular H-complexes they are usually accompanied by another broad OH band at \(\sim 1700\text{ cm}^{-1}\), the C band.\textsuperscript{19,20,25,26} In Figure 2 the C band can be found only for the CD\textsubscript{3}CN complex with the SiODAl group, being the strongest of the four H-complexes involved. This fact agrees with an IR spectroscopic regularity\textsuperscript{44} for molecular H-complexes in solutions:\textsuperscript{19,26} in a series of closely related X-OH-Y complexes the C band intensity increases on strengthening the acid-base interaction. On going from the H- to HD-zeolites (Figure 2), the intensity of the A and B OH bands decreases and broad, complex OD bands appear in the 1700-2300 cm\textsuperscript{-1} region due to the frequency isotopic shift. As shown for H-complexes of organic acids,\textsuperscript{19,20} H \(\leftrightarrow\) D exchange causes the A and B bands to shift to \(\sim 2000\) and \(\sim 1750\text{ cm}^{-1}\). The corresponding C OD band has not been definitively resolved in the very complex 500-1500 cm\textsuperscript{-1} spectral region of these complexes.\textsuperscript{3,20} Also for zeolites the C OD band should be obscured in the 1000-1300 cm\textsuperscript{-1} region of the antisymmetric lattice vibrations.
Neither the OH nor the OD bands (Figures 1 and 2) can be directly used to check whether the transmission window position between the A and B bands corresponds to the in-plane bending overtone. For the perturbed SiOHAl and SiOHFe groups this window is well-pronounced in the spectra at \( \sim 2600 \text{ cm}^{-1} \) (Figure 2 as an example), but the corresponding \( \delta(\text{OH}) \) in-plane bending band falls in the 1000–1300 \text{ cm}^{-1} region of lattice vibrations (see Figure 3). This makes the zeolitic OH groups
useless for the following consideration. For the perturbed SiODAl and SiODFe groups the δ(OD) band is well-defined (Figure 1), but the 1800–2000 cm⁻¹ region, where the corresponding Evans window is expected to appear, according to the 2xδ(OD) frequencies (Table 2), is strongly complicated by two intense lattice bands at 1880 and 2007 cm⁻¹ (Figure 3). Also in the difference spectra this region remains too complex for a definitive interpretation as the subtraction of the 1880 and 2007 cm⁻¹ bands of the unloaded zeolites from these slightly shifted by the adsorption produces “imaginary” positive and negative bands here (Figure 2 and the inset in Figure 3). This complication of difference spectra through the 1880 and 2007 cm⁻¹ bands is usual for IR experimental studies of adsorption on zeolites. A unique procedure of separation of the (A,B) OD doublet of interest from these two bands is suggested below.

The spectra recorded after the adsorption on the deuterated and hydrogen forms of zeolites in the 1800–2000 cm⁻¹ region (Figure 2) can be written, respectively, as

\[ S_D^d = S_{OD}^d + S_L^d + S_{OH}^d \]  

and

\[ S_H^b = S_{OH}^b + S_L^b \]  

\[ S_{OD}^d \] can be written as

\[ S_{OD}^d = (S^d - S^b) - (S_{OD}^d - S_{OH}^d) \]  

As \( S_{OH}^d \) and \( S_{OH}^b \) are smooth low-frequency tails of the OH bands in the 1800–2000 cm⁻¹ region (see Figures 2 and 3), the term \( (S_{OD}^d - S_{OH}^d) \) can be neglected in (5), being capable of changing only a base line of the \( S_{OD}^d \) spectra. In Figure 4 the \( S_{OD}^d \) curves are presented for the CD₃CN adsorptions on H-ZSM5 and H/D-FeSil, constructed as

\[ S_{OD}^d = (S^d - S^b) \]  

The transmission windows become clearly observable in these spectra at 1977 and 2002 cm⁻¹, very close to their expected values of 2x988 = 1976 and 2x950 = 1900 cm⁻¹ (see Table 2) according to the resonance theory. This verifies the hypotheses by Claydon and Sheppard about the nature of the (A,B) doublet. The negligible difference between the window positions and the 2xδ(OD) values is an indication of a very small value of the anharmonicity constant,

\[ \chi_{sd}^{OD} = (2\delta(OD) - 2x\delta(OD))/2 \]  

for the hydrogen-bonded OD groups. In an ab initio study by Mix et al. the \( \chi_{sd}^{OD} \) of the free zeolitic OH groups was found to be equal to ~4 cm⁻¹. This shows the contribution to the potential curve of the bending vibration from the H bonding to be harmonic with high precision. In agreement with ref 20, the transmission windows between the A and B bands are significantly narrower for the D-complexes compared with the H-complexes (cf. Figures 2 and 4).

The same procedure of the \( S_{OD}^d \) construction for the CCl₃CN adsorption on H/D-ZSM5 and H/D-FeSil (the spectra are not presented) shows that this molecule is not basic enough to provide the shift of the \( \nu(OD) \pm k\nu(OD-B) \) band to the 1800–2000 cm⁻¹ region of the 2δ(OD) overtone.

**Conclusion**

The IR study of CD₃CN and CCl₃CN adsorption on H/D-ZSM5 and H/D-FeSil zeolites shows the ~2800 and ~2400 cm⁻¹ OH bands found in adsorption of many basic molecules on zeolites to be analogous to the so-called A and B OH bands of strong molecular H-complexes in solutions, liquids, and solids. A direct experimental proof of the resonance theory of these bands by Claydon and Sheppard is suggested. According to this theory the A and B bands of medium-strong X=OH=Y complexes are actually pseudobands caused by the subdivision of the very broad OH stretching band by Evans transmission window at the 2δ(OH) bending overtone frequency.

**Acknowledgment.** We thank Dr. G. Vorbeck (Eindhoven University of Technology) for preparation of the samples.

**References and Notes**

(47) The subtraction of spectra of the unloaded H-zeolites from spectra of these zeolites to be independent of the H of the corresponding H/D-zeolites produces the "zero-intensity" line in the 1880 and 2007 cm⁻¹ bands of these zeolites to be independent of the H-D exchange.

(44) This can be inferred also from an experimental finding by Odinokov et al.⁴⁸ that in series of closely related X=OH=Y complexes the "center of gravity" of the A + B + C band shifts to lower frequencies on strengthening the H bond. The "center of gravity" is defined²⁶ as the crossing point of the subareas with equal integral intensity. It should approximately correspond to the wavenumber of the maximum of the ν(OH) band in the absence of the resonance interactions generating the Evans windows.²⁶
