Abstract

Reuse in the context of scientific simulation applications has mostly taken the form of procedural or object-oriented libraries. End users of such systems are however often non software experts needing very simple, possibly interactive ways to build applications from domain-specific components and to control their parameters. Integrating independently written (existing or new) code as components should ideally be a simple, possibly automated black-box process. We propose a dataflow-based component framework for simulation and visualization in which large existing C++ application libraries were easily integrated as interactively manipulable components by using a meta-layer object-oriented component abstraction. The path from user-level requirements to the framework design and implementation decisions is outlined.

1 Introduction

Designing open systems for scientific visualization and simulation (VisSym) has become crucial for disciplines such as computational fluid dynamics (CFD), medical sciences, or numerical analysis. As simulations' complexity has grown, the amount and variety of software elements involved in their design has increased considerably. In consequence, VisSym software architectures strive to evolve from problem-specific, monolithic applications to general-purpose frameworks offering interactive application monitoring and control and simple mechanisms to plug in various domain-specific software.

Component-based frameworks seem ideal for the above task as they decouple component manufacturing from component usage. The latter is reduced to a simple operation of connecting matching components and having the framework enforce their correct cooperation via some standard protocol. Most of VisSym end-users are not programming experts, so frameworks should provide simple, interactive ways to load various components and connect them to produce the desired application without having to program. The components' parameters should be easily controllable interactively in order to steer the running simulations, and results should be available in real-time. Finally, the large amounts of existing scientific software libraries should be easily integrable in such frameworks as components, without having to modify their often unavailable source code.

However, due to several factors, designers have been so far reluctant to adopt component-based designs. Firstly, the above constraint combination is hard to satisfy, so virtually all existing VisSym frameworks mostly use white-box inheritance techniques, and are thus notoriously limited and difficult to use by researchers that need to focus on the modelled problem and not on the often intricate software integration techniques. Secondly, the extra indirections introduced by loosely coupled designs were considered too expensive for the interactive behavior of VisSym applications.

We addressed the above issues by designing VISION [15], a component-based VisSym framework based on an object-oriented component model which extends the C++ class notion non-intrusively, in a black-box manner. Based on this component notion, we provide an easy way to build components from existing C++ class libraries, an interactive, programming-free manner to load, instantiate and connect them to create applications, and automatically built graphics user interfaces (GUIs) for for component parameter control and visual monitoring.
1.1 Requirements and User Roles

In VisSym, frameworks strive to satisfy the requirements of three user roles, or viewpoints, in the terminology of Alencar et al.[1]. End-users (EU), mostly non-programming experts, need virtual cameras, GUIs, and sometimes scripting languages. Application designers (AD) build the EU application by assembling predefined domain-specific components and work best if this assembly process is supported by a visual, interactive tool. This is usually done by connecting the components in a directed graph called a dataflow network. As the simulation runs, data flows from its source through components that process it up to the visualization components [10, 2]. The component developer (CD) forms the third user category: he builds application libraries by writing or often reusing existing code. The CD requires that existing code should be easily extensible and reusable as application components, and that the system loading the components should not constrain their design. Most frameworks address the CD’s requirements by supporting some form of object-oriented components. By OO component, we shall further denote an OO software entity directly reusable in the context of a given framework. Often the same person cycles through all the roles (e.g. a researcher who develops his code as a CD, then builds a test experiment as an AD, and steers the final application as an EU). The cycle is repeated, as end-user insight triggers application re-design for the AD, which may induce component changes, a task for the CD. As the same person must quickly and frequently switch roles, frameworks should not only offer freedom for each individual role, but also an ideally automatic way to make the work of a role immediately available to the next role.

1.2 Limitations of Current Frameworks

Matching the above requirements to the most known VisSym frameworks, we identified the following limitations:

1.2.1 Extensibility and Reuse Problems

While OO libraries written in e.g. C++ or Java are easily extensible by subclassing (e.g. vtk[16] and Open Inventor [11] for C++ or Java3D for Java [7]), most frameworks require relinking or recompilation to use new component versions. They also often force components to inherit from a common root class (hierarchies having different roots are not accepted) or use only single inheritance (SI) in e.g. the C++ case [11, 10, 16]. White-box frameworks based on inheritance or other compile-time schemes that check the validity of components by checking their interface conformance are thus the most common.

1.2.2 Inflexible I/O Typing

By providing typed inputs and outputs for components (also called ports in the dataflow terminology), VisSym frameworks assist the AD with run-time type checking to forbid connections between incompatible types. However, most frameworks’ run-time type systems have only a few basic types (integer, float, string, and arrays of these), and are not extensible with user defined types. By value and by reference data passing are also rarely both supported in the same framework. To provide run-time data conversion from one type to another, explicit conversion modules [2,16] or complicated run-time schemes to register conversion functions [11] are used, instead of more elegant schemes present in some programming languages such as conversion operators or copy constructors, or of other meta-level object protocols that could negotiate data conversions more flexibly.

1.2.3 Intrusive code integration

Frameworks take a limited number of run-time decisions so are often simpler than full-fledged compilers or interpreters. The development language is often richer in concepts than the target framework, so CDs are forced to change their code to match the system’s standard (e.g. give up multiple inheritance, pass by value, etc). Some frameworks require the components to be interfaced in a language different from the development one (e.g. tcl used by [16, 10] to interface C++ classes), thus the manual creation of wrapper classes or "glue" code [1]. Sometimes the CD must add system-specific code to his components to add dataflow and GUI functionality [2, 5, 14], which is yet another form of white-box composition. Many researchers reported that otherwise well-designed OO libraries could not be integrated in VisSym frameworks due to the need to intrusively adapt their (sometimes unavailable) source code or need to build complex wrappers.

1.2.4 Different Run-Time and Compile-Time Languages

Most VisSym frameworks implement their components in native executable code for speed reasons, and offer the EUs interpreted languages to quickly set up experiments or issue various commands. Component devel-
development languages are often different and usually more powerful than the run-time ones (e.g. tcl for [10], V for aw, di for [2]), making some features of the latter unavailable in the former, and forcing the CD to learn two languages.

### 1.2.5 Manual GUI Construction

Even though GUIs could be automatically created from the components specification, the CD usually has to manually program (or interactively build [2]) the GUIs for the developed components. Moreover, the GUIs of most frameworks support editing only a few basic types (integers, strings, floats). There is no support for editing user-defined types (e.g. a 3D vector) or user defined GUI widgets (e.g. a 3-dimensional virtual spaceball).

## 2 Overview of VISSION

Analyzing the presented limitations, it seems that most of them are caused by a very limited, ad-hoc notion of components, usually the result of the evolution of simple code integration schemes used in early systems. However, requirements as dynamic, transparent integration of independently developed OO class libraries definitely ask for black-box integration, supported by mechanisms such as dynamic code loading and reflection. The fact that many VisSym frameworks do not promote a clear identity for components, separate from and semantically higher than the computational code they extend, forces white-box composition with all its known problems.

Our solution employs the C++ language in compiled form for the development of component libraries, and in interpreted form for the application developer and the end user. VISSION's kernel is a C++ interpreter [4] able to call C++ compiled code from dynamically loadable user-written libraries, execute on-the-fly synthesized C++ code, and offer a reflection API. This allows us to completely merge the OO and dataflow modelling concepts in a new abstraction called a *metaclass*, which extends a C++ class with dataflow semantics to create our framework's component.

Component libraries are loaded in VISSION where the AD interactively builds dataflow networks using a visual programming mouse-based GUI for component instantiation, cloning, destruction, port connections and disconnections (Fig. 3) performed on iconic representations of metaclass instances. The icons for the metaclasses and their instances, as well as the GUIs used for monitoring and modification of port values, are automatically constructed by VISSION from the metaclass specification (Fig. 4).

### 2.1 The Metaclass Concept

A metaclass is a programming construct written in a simple object-oriented declarative language. It adds a dataflow interface to a C++ class: a description of the inputs, outputs, and update method, i.e. the code to be executed by the dataflow engine when the inputs have changed. The metaclass inputs, outputs and update are forwarded to the public interface of the C++ class it extends: when an input is written into, a C++ class method is called to perform the write or a public member is written; when an output is read from, a method is called and the return value is used or a public member is read. Inputs and outputs are typed by the C++ types of their underlying methods or members. Metaclasses are object-oriented since they can inherit inputs, outputs and the update methods from other metaclasses (single, multiple and virtual inheritance are supported) similarly to their underlying C++ classes, so a metaclass hierarchy is isomorphic to the C++ hierarchy it extends. We added however some OO features present in C++ to the metaclass language, e.g. the selective hiding or renaming of inherited features, similar to the approach described by Meyer in [9]. This proved very useful when managing complex metaclass hierarchies. Metaclasses of non abstract C++ classes with public constuctors can be instantiated to create *meta-objects* which are connected to form the dataflow network. A metaclass is ultimately an object-oriented type for the dataflow mechanism, implemented in terms of the C++ class type (Fig. 1).

Fig. 2 shows two C++ classes of a larger hierarchy and their metaclasses: the IVSoLight metaclass has three inputs for a light's color, intensity, and on/off value, modelled by the corresponding C++ class's methods with similar names, and of types IVSbColor (a RGB color triplet), float, and respectively boolean. <td>module IVSoDirectionalLight extends IVSoLight with an input for the light's direction, of type IVSbVec3f (a 3-space vector). Besides the port to C++ member mapping, metaclasses specify other non-functional requirements such as the labels to be used in their automatically constructed GUIs (Fig. 4), optional widget preferences (for the intensity, a slider is preferred to a typein in the above example), and documentation data that can be accessed on-line. Appropriate widgets are automatically created based on the ports' C++ types (3 float typeins for IVSbColor and IVSbVec3f, a toggle for the boolean, and a slider, as the user option specified, for the float). The requirements and limitations listed in Sect. 1.2 are addressed as follows:</td>

Figure 2: Example of C++ class hierarchy and corresponding metaclass hierarchy

2.1.1 Extensibility and Reuse

The CD develops his application C++ classes with no restriction imposed by VISION (no common root class required, multiple and virtual inheritance can be used, etc) and organizes them in application libraries. Extra information is next added by writing the metaclass descriptions for the C++ classes in a straightforward fashion (the metaclass language has only a few keywords and very simple declarative constructs). Metaclasses are organized in libraries using the C++ application libraries as implementation only via their public interfaces, introducing a first level of black-box reuse. Metaclass libraries can include other metaclass libraries and metaclasses from one library can inherit from metaclasses in other libraries, similarly to Java packages. When VISION dynamically loads a metaclass library, metaclasses from directly and indirectly included libraries are transparently loaded, together with their corresponding C++ classes. This is a second level of black-box reuse between the framework and the metaclass libraries.

2.1.2 Flexible I/O Typing

Data flow between ports is based on the full OO typing of C++: it can be passed by value, by reference, and can be of any type (fundamental or class). For class types, constructors and destructors are automatically called when data flows from an output to an input. Port connection type checking obey all C++ typing rules: a port of C++ type A can be connected to a port of type B if A conforms to B by trivial conversion, subclass to baseclass conversion, user-defined constructor and conversion operator [12]. This generalizes the dataflow typing policies of other systems: The Orange system [10], based on Objective C, offers by-reference but no by-value data passing. AVS/Express [2] limits the run-time data types to the ones provided by its OO V language which lacks constructors, destructors, and multiple inheritance. Compiled toolkits as Open Inventor [11] and vtk [16] are only statically extendable, as all types have to be known at compile time.

2.1.3 Non-intrusive code integration

All information needed to promote a C++ class to a metaclass directly usable by VISION resides in the metaclass. The metaclass-C++ class pair is roughly similar to the handle-body idiom [3], the Adapter pattern [6] or the customizable adapters presented by Kucuk et al [8], but is much easier to do than e.g. manual Adapter coding as the parallel hierarchies are managed automatically by the system, not the user. Separating the dataflow information in the metaclass allows adding dataflow semantics to existing class libraries, even when they are not available in source form. This separation between the pure, framework-independent code and the 'adaptation' layer including framework specific elements such as non-functional requirements is advocated by many [6],[13], as it allows code to be
The dataflow network is build in the visual editor by instantiating the loaded metaclasses easily reused in various contexts as its design is not influenced by the target environment.

Moreover, since the metaclass specification code is simply parsed by vision, it is very easy and fast to change it to e.g. adapt different C++ classes (e.g. having different interfaces) or adapt the same classes differently (e.g. define ports or the update to call back on other C++ methods). In this sense, our adaptation method is different from other solutions. The metaclass code might be seen as partially white-box (since it has explicit dependencies on the C++ classes’ interfaces), but it has practically none of the white-box drawbacks, since it comes in a very easy to edit/change form and not as binaries.

2.1.4 Single language solution

C++ is vision’s single language: application libraries are written in C++, the metaclass ports are typed also in C++, C++ commands can be typed in a console to be dynamically interpreted (obviating the need for a scripting language). We implemented also a generic persistence mechanism which saves all meta-object input port values and connections as C++ source code commands and restores the state by simply interpreting the saved code. The fact that our metaclass state is completely intrinsic supports once more the idea that components should be designed independently on the context in which they are used.

2.1.5 Automatic GUI Construction

VISION automatically builds GUI interaction panels (shortly interactors) to examine and modify the values of any metaclass’s ports. Interactors create the system’s third object, isomorphic with the C++ class and the metaclass hierarchies: an interactor inherits the widgets from the interactors of its metaclass’ bases. The three hierarchies correspond to the three user classes: EUs are concerned with the interactors, ADs with the metaclass interfaces, and CDs with the C++ classes. The interactor widgets reflect directly the C++ types of the edited ports. For example, a float port can be edited by a slider, a char* port by a text type-in (Fig. 4), a three-dimensional VECTOR port by a 3D widget allowing direct manipulation of a 3D vector icon (Fig. 5 c), a boolean by a toggle button, a complex Material class encoding over 15 attributes by a Material widget (Fig. 5 c), and so on. VISION’s widget set for the fundamental C++ types is extendable by the AD with widgets for new, application-specific C++ types. We used this mechanism to provide GUI widgets for C++ types used by various libraries we included in vision, such as 3D vectors, colors, rotation matrices, and light values. Type-specific widgets are loaded and unloaded with the metaclass libraries defining their types, so they can also be seen as black-box components from the framework’s point of view.
