Abstract. We investigate the deep structure of a scale space image. We concentrate on scale space critical points—points with vanishing gradient with respect to both spatial *and* scale direction. We show that these points are always saddle points. They turn out to be extremely useful, since the iso-intensity manifolds through these points provide a scale space hierarchy tree and induce a “pre-segmentation”: a segmentation without a priori knowledge. Furthermore, both these scale space saddles and the so-called catastrophe points form the critical points of the parameterised critical curves—the curves along which the spatial critical points move in scale space. This enables one to localise these two types of special points relatively easy and automatically. Experimental results concerning the hierarchical representation and pre-segmentation are given and show results that correspond to a fair degree to both the mathematical and the intuitive forecast.

Keywords: scale space, catastrophe theory, critical points, topology, deep structure, multi-scale segmentation

1. Introduction

1.1. Scale Space

One way to understand the structure of an image is to embed it in a one-parameter family. If a scale-parametrised Gaussian filter is applied, the parameter can be regarded as the “scale” or the “resolution” at which the image is observed. The resulting structure has become known as *linear*, or *Gaussian*, *scale space*. In view of the rich literature on this subject we will henceforth assume familiarity with the basics of Gaussian scale-space theory [11, 18, 20, 28, 40, 47, 51, 56, 57, 59].

1.2. Deep Structure

In their original accounts both Koenderink [28] and Witkin [59] proposed to investigate the “deep structure” of an image, i.e. *structure at all levels of resolution simultaneously*. Encouraged by the results in specific image analysis applications, an increasing interest has recently emerged in trying to establish a generic underpinning of deep structure. This may serve as a basis for a diversity of multiresolution schemes. Such bottom-up approaches often rely on *catastrophe theory* [1, 14, 42, 48, 52, 53], which is now fairly well-established in the context of the scale-space paradigm.

1.3. Related Work

The application of catastrophe theory in Gaussian scale space has been studied by Damon [8]—probably the most comprehensive account on the subject—as well as by many others [15, 16, 21–25, 29–33, 37–40, 45, 49].

An important stage in using the deep structure is to link image properties of two subsequent resolution scales. Although this may seem obvious, it is a non-trivial task in a discrete scale space. For example, if extrema at different scales correspond to an extremum at the input image, they should be linked. However, extrema may be annihilated or created. Tracking over scale therefore needs a cautious approach.

Koenderink [28] mentioned a possible linking strategy using the properties of the Gaussian scale space. Only a few heuristic attempts have been made to build such multi-scale datastructures.

Vincken et al. constructed a hyperstack segmentation algorithm [54]. Simmons et al. [50] used the idea of Koenderink's scheme for building a so-called extremum stack. Their work was an extension of the results by Lifshitz and Pizer [37], who implemented Koenderink's scheme, mainly focusing on heuristics and the performance of the algorithm.

The idea of tracing critical points and using the location where they vanish as input for a hierarchy tree was also proposed and implemented by Zhao and Iijima [60], cited in [58], and by Wada and Sato [55].

Olsen implemented a segmentation algorithm based on multi-scale watersheds [44–46].

These datastructures generally use the property of annihilation of extrema at increasing scale. However, the possibility of creations is ignored and consequently not implemented.

As an outcome of the use of catastrophe theory, much effort has been put into investigation of annihilations. It has commonly been accepted that these special points form the crux in understanding the deep structure, although it is not clear how to use them. It has been argued by several authors [19, 28, 37, 39, 40], to use the intensity at the annihilation point. Preliminary results of this paper were given by Kuijper and Florack in [35].

1.4. Aim

The aim of this paper is to investigate the deep structure of Gaussian scale spaces. We show that this results in an unambiguous hierarchical representation of an

arbitrary image. For that reason we combine knowledge from catastrophe theory, the multi-scale linking strategy as suggested by Koenderink [28], and properties of linear scale space. For that reason we introduce the so-called scale space saddles. In Section 2 we show that these scale space saddles are the key to explore the deep structure of scale space images. They give rise to an unambiguous multi-scale hierarchy describing the image. Images in one dimension fundamentally differ from those in higher dimensions, since only in 1D images the scale space saddles coincide with the catastrophe points. Therefore both cases are discussed separately. In the appendix we clarify the theory by discussing the generic annihilation event and the appearance of scale space saddles in its neighbourhood. The scale space saddle approach leads to a non-heuristic hierarchical multi-scale data structure and a segmentation of images without any a priori knowledge and is presented in Section 3. Several examples of our approach on simple artificial images and a 2D MR image are shown in Section 4. Main conclusions and results are given in Section 5.

2. Theory

The linearity of a Gaussian scale space enables us to treat the scale parameter as a special variable. For that purpose we describe in this section relevant results known from the literature (Section 2.1) and present new theory based on the critical points in scale space (Section 2.2), critical curves (Section 2.3), and iso-intensity manifolds (Section 2.4), for which purpose we need the following definitions:

Definition 1. $L(\mathbf{x})$, $\mathbf{x} \in \mathbb{R}^n$, denotes an arbitrary n -dimensional image. We will refer to this image as the *initial image*.

Definition 2. $L(\mathbf{x}; t)$, $(\mathbf{x}; t) \in (\mathbb{R}^n; \mathbb{R}^+)$ denotes the $(n + 1)$ -dimensional *Gaussian scale space image* of $L(\mathbf{x})$, i.e. $\lim_{t \downarrow 0} L(\mathbf{x}; t) = L(\mathbf{x})$.

Definition 3. Spatial critical points, i.e. saddles and extrema (maxima or minima), at a certain scale t_0 of $L(\mathbf{x}; t)$ are defined as the points at fixed scale t_0 where the spatial derivatives vanish: $\nabla L(\mathbf{x}; t_0) = \mathbf{0}$. We will refer to these points as *spatial critical points* to distinguish them from scale space critical points, see Definition 4.

Definition 4. *Scale space critical points* of $L(\mathbf{x}; t)$ are defined as the points where both the spatial derivatives and scale derivative vanish: $\nabla L(\mathbf{x}; t) = \mathbf{0}$ and $\partial_t L(\mathbf{x}; t) = 0$. Since for Gaussian scale spaces the diffusion equation holds, the latter equation equals $\Delta L(\mathbf{x}; t) = 0$, denoting a zero Laplacean.

Definition 5. A *critical curve* is a one dimensional manifold in the $(\mathbf{x}; t)$ (scale) space on which $\nabla L(\mathbf{x}; t) = \mathbf{0}$.

Note that the intersection of all critical curves with a certain scale space level t_0 results in the spatial critical points of $L(\mathbf{x}; t_0)$.

Definition 6. The *Hessian* is the matrix of second order spatial derivatives: $H = \nabla \nabla^T L$.

Definition 7. A *branch of a critical curve* is a subset of a critical curve on which the sign of determinant of the Hessian doesn't change.

Definition 8. A *Iso-intensity manifold* is an n -dimensional manifold in the $(\mathbf{x}; t)$ scale space on which $L(\mathbf{x}; t) = c$, $c \in \mathbb{R}$.

2.1. Deep Structure in Gaussian Scale Space

2.1.1. Catastrophe Theory. The behaviour of critical points as the (scale) parameter changes is described by catastrophe theory. As the parameter continuously changes, the critical points move along critical curves. If the determinant of the Hessian does not become zero, these critical points are called *Morse critical points*. In a typical image these points are extrema (minima and maxima) or saddles. *The Morse lemma* states that the topology of a neighbourhood of a Morse critical point can essentially be described by a second order polynomial. At isolated points on a critical curve the determinant of the Hessian may become zero. These points are called *non-Morse points*. As described by *Thom's theorem* [52, 53], neighbourhoods of such points need m th-order polynomial, where $m > 2$. These polynomials are called the *catastrophe germs*. If an image is slightly perturbed, the Morse critical points may undergo a small displacement, but qualitatively nothing happens to them. A non-Morse point, however, will change. It will split into a non-Morse point that can be described by a polynomial of lower order and a number of Morse critical points, or solely into Morse critical

points. This event is called *morsification*. Thom's theorem provides a list of elementary catastrophes with canonical formulas¹ for the catastrophe germs and the perturbations. The Thom splitting lemma states that *canonical coordinates* exist in which these events can be described. In general, these 'curved' coordinates don't coincide with the user-defined (usually Cartesian) coordinates, but are used for notational convenience. In Gaussian scale space the only generic events are *annihilations* and *creations* of a pair of Morse points: an extremum and a saddle in the 2D case. All other events can be split into a combination of one of these events and one 'in which nothing happens'. See Damon [8] for a proof. Canonical descriptions of these events are given by the following formulae:

$$f^A(\mathbf{x}; t) \stackrel{\text{def}}{=} x_1^3 + 6x_1t + Q(x_2, \dots, x_n; t) \quad (1)$$

$$f^C(\mathbf{x}; t) \stackrel{\text{def}}{=} x_1^3 - 6x_1(x_2^2 + t) + Q(x_2, \dots, x_n; t), \quad (2)$$

where for all $a_i \neq 0$, Q is defined by

$$Q(x_2, \dots, x_n; t) \stackrel{\text{def}}{=} \sum_{i=2}^n a_i (x_i^2 + 2t)$$

with $\sum_{i=2}^n a_i \neq 0$ and $a_i \neq 0$, $2 \leq i \leq n$. Note that Eqs. (1) and (2), describing annihilation and creation respectively, satisfy the diffusion equation

$$\frac{\partial L}{\partial t} = \Delta L. \quad (3)$$

It can be verified that the form $f^A(x, y; t)$ corresponds to an annihilation at the origin via the critical path $(\sqrt{-2t}, 0; t)$, $t \leq 0$, and $f^C(x, y; t)$ to a creation via the critical path $(\sqrt{2t}, 0; t)$, $t \geq 0$.

Note that creations are generic. They are not sometimes temporarily created, nor false extrema, nor pathological cases, although it is true that they are not as frequently encountered as annihilations.

In 1-D images only annihilations occur. Then Eq. (1) becomes $f^A(x; t) \stackrel{\text{def}}{=} x^3 + 6xt$. See e.g. Lindeberg [40] for a proof.

2.1.2. Extremum Principle and Iso-Intensity Manifolds. A consequence of the Gaussian scale space representation is the strong smoothing property, usually mentioned for its *non-enhancement of local extrema*. It corresponds to the *extremum principle* for parabolic differential equations:

If at a certain scale $t_0 > 0$ a point $\mathbf{x}_0$ is a local maximum (minimum) of the function $L(\mathbf{x}; t_0)$, then the Laplacean $\Delta L(\mathbf{x}_0; t_0)$ at this point is negative (positive). This means that $\partial_t L(\mathbf{x}_0; t_0)$ is strictly negative (positive).

In other words, small local variations will be suppressed. See e.g. Lindeberg [40] or Weickert [56] for more details.

As a result, the structure of iso-intensity manifolds in scale space close to an extremum is dome-shaped: At some scale an extremum, e.g. a maximum, is encapsulated by iso-intensity manifolds (isophotes in 2D), topologically equivalent to spheres (circles in 2D). The intensity of each of these manifolds is smaller than that of the maximum. Due to the extremum principle the intensity of the maximum decreases with increasing scale. At a certain scale the intensity of the maximum will equal the intensity of some manifold. Alternatively, the shape of the intersection of the image at increasing scales and the iso-intensity manifold shrinks until it coincides at certain scale with the maximum and then disappears. In 2D this can easily be visualised by a set of circles contracting to the maximum at increasing scale: that is, the iso-intensity manifold is dome-shaped. The top of the dome corresponds to the disappearance of the iso-intensity manifold around this extremum. See Fig. 1 for an example of various iso-intensity manifolds.

Since the image at sufficiently large scale contains only one extremum (see [41]), the evolution of extrema

induces a family of iso-intensity domes, nested like onion peels.

2.2. Scale Space Critical Points

Since scale provides an extra dimension to the initial image, interesting features are to be expected from the critical points of the scale space image as defined by Definition 4. In this and the following sections we present novel theory regarding these points.

The scale space critical points are defined as the points in scale space with zero gradient and zero Laplacean:

$$\begin{cases} \nabla L(\mathbf{x}; t) = 0 \\ \Delta L(\mathbf{x}; t) = 0 \end{cases}$$

since $\partial_t L(\mathbf{x}; t) \stackrel{\text{def}}{=} \Delta L(\mathbf{x}; t)$. The type of these scale space critical points is determined by the eigenvalues of the matrix of second order derivatives in scale space, $\mathcal{H}$. We call this matrix the *extended Hessian*:

$$\mathcal{H} = \begin{pmatrix} H & \Delta \nabla L \\ (\Delta \nabla L)^T & \Delta \Delta L \end{pmatrix}. \quad (4)$$

Here H is the (spatial) Hessian. All derivatives are evaluated at the location of the scale space critical point of interest. Points are maxima (minima) if all eigenvalues are negative (positive). If at least two eigenvalues have a different sign, the point is a saddle. $\mathcal{H}$ has the following properties:

- Since the matrix $\mathcal{H}$ is symmetric all eigenvalues are real.
- At scale space critical points $\text{tr } H \equiv \Delta L = 0$, so $\text{tr } \mathcal{H} = \Delta \Delta L$.
- $\det \mathcal{H} = \det H \Delta \Delta L - ((\Delta \nabla L)^T \tilde{H} \Delta \nabla L)$, where $\tilde{H} \stackrel{\text{def}}{=} \det H \cdot H^{-1}$, the transposed co-factor matrix of H . In fact, this matrix is always well-defined, since its components are homogeneous polynomial combinations of the components of H of degree $n - 1$, see [12, 34]. So at catastrophe points $\tilde{H}$ is generically non-zero, although $\det H = 0$. At these points $\det \mathcal{H}$ reduces to $-((\Delta \nabla L)^T \tilde{H} \Delta \nabla L)$, which is equal to the generically non-zero invariant $-\Delta L_i \Delta L_j \tilde{H}_{ij}$ (summation convention applies).
- The determinant of $\mathcal{H}$ can also be written as

$$\det \mathcal{H} = ((\Delta \nabla L)^T; \Delta \Delta L) \cdot \begin{pmatrix} -\tilde{H} \Delta \nabla L \\ \det H \end{pmatrix}$$

Figure 1. Intersections of 2D iso-intensity surfaces and the critical curve. Top left: Dome-shaped—one intersection. Top right: Through the scale space saddle, two touching manifolds—two intersections. Bottom left: Dome-with-hole: intensities between the scale space saddle and the catastrophe point—three intersections. Bottom right: Horseshoe surface through the catastrophe point—two intersections.

Here the component $((\Delta \nabla L)^T; \Delta \Delta L)$ is the normal vector of the plane with constant Laplacean. The component $(-\tilde{H} \Delta \nabla L; \det(H))^T$ denotes the (scale space) tangent of the critical curve in scale space at the spatial critical points. It is always finite in value, even at catastrophe points. See Florack and Kuijper [12, 34] for more details.

- Scale space critical points are always scale space saddle points. See Theorem 1.

Theorem 1. *The matrix $\mathcal{H}$ has both positive and negative eigenvalues at scale space critical points.*

Proof 1: Let the point $(\mathbf{x}_0; t_0)$ be a scale space critical point of the function $L(\mathbf{x}; t)$. Then $(\mathbf{x}_0; t_0)$ is also a spatial critical point of the function $L(\mathbf{x}; t_0)$ at scale t_0 . If $(\mathbf{x}_0; t_0)$ is a scale space extremum of $L(\mathbf{x}; t)$, it is also a spatial extremum of $L(\mathbf{x}; t_0)$. However, the extremum principle (Section 2.1.2) states that the Laplacean of a spatial extremum is non-zero, leading to the contradiction that $(\mathbf{x}_0; t_0)$ cannot be a scale space critical point. Therefore $(\mathbf{x}_0; t_0)$ is a scale space saddle point. Consequently, $\mathcal{H}$ has both positive and negative eigenvalues at scale space critical points. $\square$

As a consequence, critical points in scale space ($\nabla L = 0$ and $\Delta L = 0$) are *always* saddle points. These scale space saddle points form a subset of the spatial saddles, viz. those with vanishing Laplacean.

This property of scale space critical points follows directly from the notion of causality, that states that isophotes in scale space only disappear and never appear (no spurious detail).

The only spatial critical point traversing the scale space saddle is the spatial saddle. Since the manifold $\nabla L = 0$ intersects the manifold $\Delta L = 0$ transversally, the intensity of this spatial saddle has an extremum at the scale space saddle. Therefore, its intensity first increases and then decreases, or vice versa. This is exactly the behaviour Lifshitz and Pizer observed, see [37]. We elaborate on this behaviour in Section 2.3 and go into details in the appendix.

2.3. Properties of Critical Curves in Scale Space

According to Definition 7, in scale space each critical curve contains branches representing spatial critical points. Branches are connected at catastrophe points, where two spatial critical points are annihilated or created. These two spatial critical points differ with respect to the sign of one eigenvalue of the Hessian, that

becomes zero at the catastrophe. Of all other eigenvalues the number of positive and negative signs is equal. Note that a critical curve can contain several catastrophe points if $n > 1$.

In two-dimensional images the two branches connected at catastrophe points necessarily are a saddle and an extremum branch, in one-dimensional images they are a maximum and a minimum branch. In higher dimensions interactions become more complicated, since catastrophes of saddles of different type are also possible. For writing convenience we will use the terminology appropriate for 2D images: saddle and extremum (minimum, maximum) branches to distinguish between the two types of spatial critical points involved at the catastrophe, but results remain valid for other dimensions.

It is known from catastrophe theory that each branch of the critical curve is bounded with respect to scale: at some scale the spatial critical points annihilate. Spatial critical points are either present from the initial scale or they are created at a certain (catastrophe) point in scale space. If the coarsest scale is taken large enough only one extremum remains. Then the scale space image contains one critical curve bounded by the coarsest scale.

Apart from catastrophe points a second type of points exhibits special behaviour, viz. scale space saddles.

2.3.1. Scale Space Saddles. On an extremum branch the intensities are damped continuously while increasing scale. Each minimum (maximum) intensity therefore increases (decreases) monotonically towards the intensity at the annihilation point. At certain spatial and scale distance from the annihilation, the intensity of corresponding saddle will generally tend to move towards the intensity of extremum, i.e. it decreases (increases) to the intensity of minimum (maximum). So the signs of the Laplacean of both spatial critical points at that scale will be opposite. At the catastrophe point, however, they necessarily have the same sign and both points approach the intensity of the annihilation in a decreasing (increasing) fashion.

This was observed by Griffin, who pointed out that at a catastrophe the saddle and the extremum necessarily have the same sign of the Laplacean. He distinguished between ridge and trough saddles. Saddles may change from ‘ridge’ (negative Laplacean) to ‘trough’ (positive Laplacean) or vice versa with increasing scale and generically occur as ‘balanced’ saddle (zero Laplacean) [15, 16].

Therefore, at the saddle-branch of the critical curves, the saddle will generically pass a point at which the Laplacean equals zero: a scale space saddle. Since the sign of the Laplacean changes while passing the scale space saddle, the intensity on the saddle branch has a local extremum.

2.3.2. Parametrisation. A parametrisation of a critical curve leads to a 1D-function of the intensity of the spatial critical points.

Definition 9. Let $(\mathbf{x}(s); t(s))$ be a parametrisation of $(\mathbf{x}; t)$, such that $\nabla L(\mathbf{x}(s); t(s)) = 0$, i.e. $(\mathbf{x}(s); t(s))$ defines a critical curve. Then the intensity of the parametrised curve $P(s)$ is defined by $L(\mathbf{x}(s); t(s))$ for a compact range $s \in [s_{\min}; s_{\max}]$.

Note that $P(s)$ can be a combination of several connected parts $P_i(s_i)$, each defined on a compact interval $[s_{i,\min}; s_{i,\max}]$. Two parts $P_i(s_i)$, $P_j(s_j)$ are connected at a catastrophe point given by either $s_{i,\min} = s_{j,\min}$ or $s_{i,\max} = s_{j,\max}$.

The local extrema of $P(s)$ have the following property:

Theorem 2. For n -D images, $n > 1$, $P(s)$ has its critical points at the scale space saddle(s) and the catastrophe point(s). They are extrema.

Theorem 3. If, for 1D images (signals), the critical point of $P(s)$ is located at the interior of $[s_{\min}; s_{\max}]$, it is a point of inflection.

Proof 2: The critical points of $P(s)$ are defined by $\partial_s P(s) = 0$. According to Definition 9, the left part of this equation equals the total differentiation of $L(\mathbf{x}(s); t(s))$ with respect to s , defined by

$$\frac{dL(\mathbf{x}(s); t(s))}{ds} = \nabla L(\mathbf{x}(s); t(s)) \cdot \mathbf{x}_s(s) + \Delta L(\mathbf{x}(s); t(s)) \cdot t_s(s). \quad (5)$$

Here

$$\mathbf{x}_s(s) \stackrel{\text{def}}{=} \frac{d\mathbf{x}}{ds}, \quad t_s(s) \stackrel{\text{def}}{=} \frac{dt}{ds}.$$

Since $\nabla L(\mathbf{x}(s); t(s)) = 0$, the critical points of Eq. (5) are given by $\Delta L(\mathbf{x}(s); t(s)) \cdot t_s(s) = 0$. The scale space saddles are defined as the spatial critical points where $\Delta L(\mathbf{x}(s); t(s)) = 0$. The catastrophes take place at the location where the saddle and the extremum ‘meet’ in

scale space, i.e. where the parametrisation of scale has its local extrema. These points are given by $t_s(s) = 0$.

The critical points of $P(s)$ are extrema, since at the catastrophe point the Laplacean is non-zero for n -D images, $n > 1$. $\square$

Proof 3: For 1D images the zero-Laplacean and the catastrophe point coincide, so if the critical point lays in the interior of $[s_{\min}; s_{\max}]$, the solution of $t_s(s) = 0$ equals that of $\Delta L = 0$. $\square$

Although these results holds for any parametrisation of the critical curves, in practice the intensities of spatial critical points are obtained at the calculated scales of the scale space. In other words, they are measured as a function of scale. Then $t = s$, so $t_s = 1$ and $P(s)$ is obtained as the union of parts $P_i(s_i)$ containing the branches of critical points. Each branch is defined on an open interval $s_1 < s < s_2$, where s_1 is either the initial or the creation scale, and s_2 is the annihilation scale of the spatial critical point. The branches are connected at the catastrophe points, emphasising that the detection and use of creations is essential to build accurate critical paths.

In the appendix we clarify these theorems using generic events in scale space.

2.3.3. Number of Scale Space Saddles. As argued in Section 2.3.1, we may generally assume that the intensity at the annihilation of an extremum-saddle pair lays between the intensities of both spatial critical points at a certain scale below the annihilation scale. Then the spatial critical points have opposite signs of Laplacean and the saddle passes a scale space saddle with increasing scale. The number of scale space saddles on a saddle branch of a critical curve is, however, undetermined and the saddle branch of a critical curve can contain zero, one, or multiple scale space saddles.

This was also observed by Lindeberg [39, 40] who investigated the locations of Laplacean zero-crossings in combination with the (annihilation of) critical points concluding that in two and higher dimensions there is no absolute relation between locations of the Laplacean zero-crossing curves and the local extrema of a signal.

Intuitively the case without scale space saddles can be made clear by imagining an image of an extremum and a saddle with (already) the same sign of Laplacean.

Multiple scale space saddles on a saddle branch are caused by changing structure in the image nearby the saddle point.

Examples of this varying number of scale space saddles on a single branch can be found in Section 4.2.2.

2.4. The Structure of Iso-Intensity Manifolds

The iso-intensity manifolds of a 2D image are formed by the isophotes. These isophotes generally are Jordan curves, i.e. non-intersecting curves. If they don't end on the boundary they are closed, e.g. the isophotes around an extremum. There exist a finite number of non-Jordan curves. These curves do intersect themselves in the (spatial) saddle points of the image. Generically these curves have but one point of self-intersection. Consequently the image is separated into regions in which all isophotes are Jordan curves by the isophotes through the saddle points. This separation can be extended to arbitrary dimension.

The extension to scale space images leads to the necessity of scale space saddle points, as defined in the previous section. The iso-intensity manifolds through these points form the natural separation of parts of the scale space image. Each spatial extremum can be assigned to a spatial saddle by means of an extremum-saddle catastrophe, and consequently it can be assigned to the scale space saddle corresponding to the spatial saddle, if the saddle branch contains one, see Section 3.1.5 for more details. Each spatial extremum is encircled by iso-intensity manifolds of which the one through the scale space saddle forms the 'critical' manifold. That is: all iso-intensity manifolds beneath the critical manifold form a closed segment in scale space.

Definition 10. A *scale space segment* is defined as a part of a scale space image that is bounded by the dome part of the iso-intensity manifold through a scale space saddle; the top of the dome is the spatial extremum to which the scale space saddle has been assigned.

There are four essentially different types of iso-intensity manifolds shown in Fig. 1 and explained hereafter:

- Iso-intensity manifolds are dome-shaped and don't intersect themselves. Each dome has its open ends towards finer scale. The top of the dome lays on the extremum branch of the critical curve. Consequently, these domes encapsulate a bounded region in scale space. The dome doesn't intersect nor touch the saddle branch, see Fig. 1(a).

- The iso-intensity manifold through a scale space saddle consists of two parts, separated by the scale space saddle. One part is dome-shaped around the spatial extremum connected to the scale space saddle by the critical curve. At the scale space saddle this manifold touches another having the same intensity, see Fig. 1(b).
- Iso-intensity manifolds with intensities between the scale space saddle and the catastrophe point are still dome-shaped around the spatial extremum, but have a 'hole in the roof' around the scale space saddle. Consequently, the maximum scale at which the iso-intensity manifold occurs is not determined by the spatial extremum, see Fig. 1(c). The saddle branch is intersected twice by the iso-intensity manifold. In fact, the manifold transforms from dome-shaped to horseshoe as described in the next item.
- The iso-intensity manifold through a catastrophe point has a horseshoe shape, as is known from catastrophe theory. It touches the critical curve at the catastrophe point, see Fig. 1(d).

As a dual expression it follows that starting from the initial image, spatial extrema on a extremum branch of a critical curve form the top of a dome-shaped iso-intensity manifold in scale space that doesn't intersect itself and is present at all scales beneath the scale at which the spatial extremum occurs, until its intensity equals that of a scale space saddle on the saddle branch of the critical curve. Increasing scale, i.e. tracking the extremum further on the extremum branch, the iso-intensity manifold through the spatial extremum transforms to a horseshoe shape at the annihilation. In case of a minimum (maximum) there are only a pure domes at intensities smaller (larger) than the intensity of the scale space saddle.

3. Scale Space Hierarchy and Pre-Segmentation

In the previous section we have given a theoretical framework in which iso-intensity manifolds defined scale space segments. The manifolds through scale space saddles can be regarded as separatrices of these segments. By definition, each of the scale space segments contains at least one extremum. If a segment contains multiple extrema, it obviously contains sub-segments. Consequently, the set of scale space saddles and their iso-intensity manifolds induce both a hierarchy and a segmentation of the scale space image. These

two properties are discussed in detail in the following subsections.

3.1. Scale Space Hierarchy

A natural hierarchy results as scale space segments are defined by the regions encapsulated by the iso-intensity manifolds through the scale space saddles. This hierarchy avoids problems arising when defining a straight-forward and non-multiscale hierarchy of an image based solely on the nesting of iso-intensity contours through the spatial saddle points in the initial image. Although this nesting defines a hierarchy at some scale, it is not scale independent. Generically, spatial saddles have different intensities in the initial image since they are Morse-saddles. When scale is increased the nesting can change: At some scale levels intensities of saddles become equal. Then, for example, the isophote through a saddle contains another saddle and encircles three extrema. They form the so-called Maxwell set. Increasing scale, the nesting of the saddles swaps, see e.g. Lindeberg [40].

Since scale space saddles generically have different intensities, a unique scale space hierarchy is found using the nesting of the scale space saddle, as described by the following algorithm:

Scale Space. With the input of an n -D image, build a scale space consisting of $k + 1$ levels, $t = 0, 1, \dots, k$.

Extremum and Saddle Stacks. Find the extrema and the saddle points at each level t together with their intensities and put them in two separate stacks.

Extremum and Saddle Branches. Link each critical point location at level t to its corresponding location at level $t + 1$, $t = 0, \dots, k - 1$ and vice versa, as long as this successive location is found. This results in doubly linked lists of critical points in each stack.

Connected Critical Paths. For each list in the extremum stack find a list in the saddle stack and combine them pairwise to critical curve lists by means of these catastrophe points.

Scale Space Saddles. Find the scale space saddles and their intensities along each critical curve, i.e. find the intensity extrema of each saddle list.

Hierarchical Tree. Sort the extremum branches containing the catastrophe points from appearance at coarse to fine scales and construct the hierarchy tree starting at highest scale. While descending in scale,

each successive catastrophe denotes a critical curve with a scale space saddle and thus defines a new segment of the hierarchy tree as a sub-segment of an existing segment. That is, one branch of the tree is split into two branches in a unique way.

In the following sections these items will be explained and illustrated.

3.1.1. Scale Space. Input is a discrete image of arbitrary size and dimension. Only for the sake of illustration we consider the one- and two-dimensional cases. Images of higher dimension are comparable to the two-dimensional ones, albeit that they allow saddle-saddle pairs at catastrophes. These pairs, however, behave equivalently to saddle-extremum pairs.

A scale space image is obtained by convolving the input image with a normalised Gaussian filter of variable size. The intermediate levels are logarithmically sampled, see e.g. [11, 17, 18, 28, 31, 40, 43, 51].

3.1.2. Extremum and Saddle Stacks. Each level in scale space is a blurred image. Its spatial critical points can be calculated by various methods, e.g. zero-crossings of the derivatives, winding-numbers (see [25]), or neighbourhood-relations. The latter has several implementations. For 2-D images Bloms method [3, 4] may be preferred. This method uses a hexagonal lattice based scheme, in which the intensity of each point is compared to its 6 neighbours. The advantage of this scheme is that it finds all the saddle points and ‘respects’ the Euler number. Common pixel-based methods like the 4- and 8-neighbourhood schemes sometimes miss saddles or cluster them. However, the generalisation of Bloms method to higher dimensions is non-trivial.

Critical point locations and their intensities are stored in two stacks, one containing the saddles and one containing the extrema.

3.1.3. Extremum and Saddle Branches. Since critical points can be annihilated and created, they inherit both movement in increasing scale direction and spatial drift. This scale space movement can be calculated accurately by means of derivatives up to third order, see e.g. [12, 34] and gives the expected location of the spatial critical point at the next scale.

So to each spatial critical point $\mathbf{x}_{i,t}$ at level t its expected location $\mathbf{x}_{i,t+1}^e$ at level $t + 1$ is assigned. To link spatial critical points at two subsequent levels, the point sets $\mathbf{x}_{i,t}$ and $\mathbf{x}_{i,t+1}^e$ are compared to the critical points

$\mathbf{x}_{j,t+1}$ at the next level. We define the distance matrices $d_{i,j}^1$ and $d_{i,j}^2$ by

$$\begin{cases} d_{i,j}^1 = \|\mathbf{x}_{i,t} - \mathbf{x}_{j,t+1}\|, \\ d_{i,j}^2 = \|\mathbf{x}_{i,t+1}^e - \mathbf{x}_{j,t+1}\|, \end{cases}$$

and set $d_{i,j} = \min(d_{i,j}^1, d_{i,j}^2)$. Next, we take $\min_{i,j} d_{i,j}$, establishing a link, and remove the row and column containing this value. The linking continues until either all points at level $t + 1$ are linked (and the matrix d has zero rank), or $\min d_{i,j}$ exceeds scale. The intensities of the points at both levels can be used for verification.

The outcome of this procedure are two stacks each containing doubly linked lists. The head of each list corresponds with the creation of the critical point (or the initial scale), its tail with the annihilation.

3.1.4. Connected Critical Paths. Since the annihilation of an extremum involves a saddle, each tail of an extremum list at a certain scale t corresponds to a tail of some saddle list at the same scale t . The same holds for creations in relation to the heads of the lists. The intensities can be used for verification.

Note that at catastrophes the spatial drift becomes undetermined since $\det(H) = 0$. Then the movement of a critical point can still be accurately predicted, see [12, 34].

Relating saddle and extremum lists results in chains of extremum-saddle sets, viz. critical curves.

3.1.5. Scale Space Saddles. Scale space saddles have the property that they are the local extrema of the parametrised intensity-curve, obtained by taking the intensity along the saddle branches as function of scale, as argued in Section 2. They are easily found by a list-operation on the saddle lists. Saddle lists can have zero or multiple extrema with respect to intensity.

If no extrema are found then the Laplaceans of the extremum and the saddle have either the same or the opposite sign at all scales on which they are found. The former signals that there was no scale space saddle in the range of used scales. One might say that it is located at a scale that is smaller than the scale of the first image of the scale space stack. To identify a segment with the extremum, the intensity of the saddle in that first image can be taken. The latter case represents a scale space saddle located closer to the catastrophe point than resolutions allows to be measured. Then the saddle at the coarsest scale is assigned as scale space saddle.

If multiple scale space saddles are found within one saddle list, the one with maximum (minimum) intensity in case of a minimum (maximum) is chosen.

Since each extremum list is linked to a saddle list, each extremum is linked to a scale space saddle containing the global intensity extremum in the saddle list. Equivalently, the iso-intensity manifold through the scale space saddle encapsulates the corresponding extremum.

3.1.6. Hierarchical Tree. The annihilations—and consequently each extremum branch—are sorted from coarse to fine scale. Each scale space saddle defines an iso-intensity manifold around an extremum: the part of the image encapsulated by this manifold is a segment of the image at that scale. Segments may have sub-segments, defined by scale space saddles within the segment.

At the coarsest scale only one extremum remains. Since it has no corresponding saddle branch containing a scale space saddle, it doesn't have an a priori critical dome. Without the presence of a saddle the iso-intensity manifolds through an extremum is obviously dome-shaped. Therefore the iso-intensity manifold of the remaining extremum can be chosen having the intensity of the extremum at the coarsest scale. Since the heat equation under suitable boundary conditions (e.g. periodic or reflecting ones) is energy preserving, it preserves the average grey value of the image. It is then known that the input image converges to an image of constant value equalling the average value of the input image. Consequently the value of the iso-intensity manifold of the remaining extremum can be set to this value.

The hierarchy tree contains as nodes the locations of the annihilations in scale space, together with their corresponding scale space saddles and their intensities. The branch to the parent corresponds to the scale space segment in which the scale space saddle is located. The branches to the children of the tree are formed by the original segment and the new segment defined by the scale space saddle. The root of the tree is defined as the one remaining extremum.

3.2. Segmentation

A natural segmentation of *scale space* is thus obtained by the iso-intensity manifolds of the scale space saddles with their corresponding extrema. Consequently, a *spatial* segmentation, or rather “pre-segmentation”, of the image at any scale t is found by the intersection of

the scale space segmentation and the image at this fixed scale t . A full (partial) pre-segmentation of the initial image is found by taking into account the intensities of all (a subset of all) scale space saddles. The word “pre-segmentation” is used to distinguish between the proposed separation of the image into topologically different parts and the commonly user-defined (and user-verified) segmentations. The latter introduce by definition prior knowledge and are therefore definitely different from our proposed pre-segmentation.

At a partial segmentation each selection of scale space saddles defines segments of the image within some grey-level range in the part of the image enclosed by the iso-intensity manifold. Knowledge of the grey-level distribution of the image may then lead to a semantical choice of scale space saddles and their corresponding segments and thus using the pre-segmentation as a pre-stage for the “real” user-defined segmentation. This partial segmentation is easily obtained by elementary tree operations, e.g. selecting or deselecting subtrees, contracting nodes in the tree, etc.

Finally, to obtain a rough segmentation, that is a segmentation based on the large structures, only the upper part of the tree with large scales can be taken into account.

4. Applications

In this section we apply the algorithm as described in the previous section to a 1D signal and to two 2D images. We present the obtained hierarchy trees and show pre-segmentations. We also give an illustration of the effect of tree operations on the pre-segmentation.

4.1. 1D Signals

As first example we use the part of a 1D signal shown in Fig. 2(a). As can be seen directly, it contains three minima and three maxima, so the scale space image contains three scale space saddles (equivalently: catastrophes, annihilations). The four topologically different appearances of this signal in scale space after successive catastrophes are shown in Fig. 2(a–d).

The scale space hierarchy tree is shown in Fig. 3. At high scales there is only one segment S_0 : the whole image from boundary to boundary, as shown on the top-right side of Fig. 3. Decreasing scale, one reaches scale space saddle 3, from which point the image contains two segments: S_1 and the complement of S_1 : the

Figure 2. 1D signal at increasing scale: (a) initial signal, (b) after the first catastrophe, (c) after the second catastrophe, and (d) after the last catastrophe.

parts that range from the boundaries to S_1 . Continuing the descent one reaches scale space saddle 2, from which point segment S_1 contains a subsegment, viz. S_2 . Decreasing scale even more one ends up with scale space saddle 1, from which point a new segment S_3 is obtained from the boundary part.

Interpreting Fig. 3 the other way round one concludes that starting with the pre-segmentation where $S_2 \subset S_1 \subset S_0$, $S_3 \subset S_0$ at increasing scale firstly segment S_3 vanishes at the boundary, secondly S_2 is “gulped down” by S_1 , and finally S_1 disappears.

The notion of disappearing of structure at annihilation points gave rise to the gist that the essence of segmenting images should be based on catastrophe points instead of scale space points. This misinterpretation is caused by the coincidence of scale space saddles and catastrophe points in 1D.

4.2. 2D Images

As 2D examples we firstly took an 81×81 artificial image, built up by the combination of four Gaussian blobs, see Fig. 4(a). Note that the four maxima induce one minimum. The simplicity of this image enables a quantitative check of the outcome. Subsequently we took a 2D slice from an artificial MR image shown in Fig. 4(b) to illustrate the use and possibilities of the hierarchy tree. This image is taken from the *Brain Web* [6, 7, 36], web site <http://www.bic.mni.mcgill.ca/brainweb>.

4.2.1. Artificial Image. The 81×81 artificial image contains five extrema. Since the image at (very) large scale contains only one blob, four extrema must be annihilated. To obtain the scale space hierarchy a scale space consisting of 113 levels was built. Levels were calculated at scales $e^{i/32}$, $i = 2, \dots, 114$ and at each level the spatial critical points were calculated. Figure 5 shows 15 levels of the stack at increasing scales together with the calculated spatial critical points.

Next, the spatial critical points of subsequent scales were linked resulting in the critical paths. Figure 6 shows the locations of spatial critical points in scale

Figure 3. Left: Hierarchy tree of Fig. 2(a), at the top coarsest scale. The three ‘Saddles’ denote the subsequent topological changes (catastrophes, annihilations) of the image as scale increases. The vertical branches denote the distinguished segments present at these scales. The stack of images at the right show the shape of the signal, changing at the three scale space saddle scales, and their pre-segmentations. Note that the lowest two are zoomed as to show clearly the distinct pre-segmentations.

Figure 4. 2D test images Left: Artificial image built by combining four maxima and one minimum. Right: 181×217 artificial MR image.

space. For visualisation purposes this $81 \times 81 \times 113$ scale space was reduced to a $41 \times 41 \times 113$ volume of interest space, since the critical points evolve in the middle of the image so a spatial border of 20 pixels was omitted. Dark grey points correspond to extrema, light grey points to saddle points. We note that at three isolated scales a pair of created and directly annihilated critical points were detected. The algorithm is able to detect these points and proposes the right linking.

The parametrised critical paths, viz. the intensities of the critical curves containing the branches of saddle and extremum branches, are shown in Fig. 7. The top row shows the branches of the saddles (left) and the extrema (right). The extrema and saddle points were pairwise grouped by means of their catastrophe points. Annihilations occur at $t = 48, 55, 66, 77$, i.e. at scales 4.48, 5.58, 7.87, and 11.1. The four catastrophes are visible as the end of two branches of critical points. At

these points saddle and extremum branches are connected forming the critical paths, see the bottom row of Fig. 7. On the left all critical curves are shown, on the right one saddle-extremum pair is taken apart.

The scale space saddles are derived from the saddle branches. It can be seen that the upper three saddle branches shown in Fig. 7, although containing multiple local extrema with respect to the intensity, have a global maximum, viz. the scale space saddle of interest. The fourth saddle branch is monotonically increasing, just as its corresponding minimum. Therefore the intensity of the spatial saddle at the first level is chosen as value for the minimum encapsulating manifold.

Finally an unambiguous hierarchy based on the catastrophe points and the scale space saddles, just as in the 1D case, can be made. The presence of 5 extrema results in 5 inner regions $S_i, i = 1, \dots, 5$ and a boundary region S_0 . The first region is defined by the remaining extremum. The scale space dome defined by this maximum is the iso-intensity manifold valued by the intensity of the extremum at coarsest scale. Since the diffusion equation is energy preserving, it thus preserves the grey value. Consequently, the value of the remaining extremum converges (down, in this case of a maximum) to the average intensity of the initial image. This convergence can also be seen in Fig. 7(b). The projection of this segment S_1 and its dual S_0 onto the initial image are shown in Fig. 8(a).

To find the next segment, scale is decreased until the second extremum appears. From the fourth row of Fig. 5 it can be seen that this segment S_2 is located at the top left part of the image. The value of the iso-intensity manifold is obtained from the scale space saddle of

Figure 5. Images from the scale space stack of Fig. 4(a). Scale increases from left to right, top to bottom. Dark dots denote extrema, bright dots saddle points.

the spatial saddle corresponding to this extremum. The intersection of this manifold with the initial image is shown in Fig. 8(b). The other segments are found in the same way, resulting in the pre-segmentation of the image as shown in Fig. 8(f).

This image, although it follows from a well-defined mathematical concept, might be counterintuitive in view of the assumed absence of a small closed region around the extremum of segment S_1 . From Figs. 4(a) and 7(b) it is clear that this extremum has almost the

Figure 6. Spatial critical points of Fig. 4(a) in (x, y, t) scale space. Dark grey points correspond to extrema, light grey points to saddle points.

same intensity as the extremum of segment S_2 , so one might expect the size of segment S_1 to be approximately the same as S_2 . However, the domes defined by the scale space saddles are nested, so essentially $S_2 \subset S_1$ and from Fig. 7 is it clear which saddle-extremum pair annihilates. Although the correct annihilating extrema can be found, it may be desirable—based on prior knowledge of the image and/or of human perceptive characteristics—to add this extra iso-intensity

manifold and thus extra segment. In the next section we give an example.

Furthermore, the hierarchy tree associated with this pre-segmentation is given by the successive annihilations in scale space, shown in Fig. 9. The nesting of segments is given by $(S_2, S_3, S_4, S_5) \subset S_1$ and the whole image is given by $S_0 \cup S_1$.

4.2.2. MR Image. Having a hierarchical description tree of the image, one can disregard parts of the tree. Combined with knowledge of the image one can thus obtain a pre-segmentation useful for e.g. further segmentation. Figure 4(b) shows a 2D slice from a simulated MR brain image.

This input image has 812 extrema and consequently at least 813 separate regions. Obviously, most of these are only defined on a small range of scales. In order to investigate the large structures of this 2D image, we focused on the part of the scale space from scales 8.37 to 33.1, exponentially sampled by 89 scales. The image on scale 8.37, which can be seen in Fig. 11(a), contains seven extrema of which six annihilate in the range up to scale 33.1. The parametrised critical paths in this scale range are shown in Fig. 10(a), the saddle branches are taken apart in Fig. 10(b).

The seven extrema define the eight segments of Fig. 11(b) in a similar fashion as in the previous subsection. This pre-segmentation of Fig. 11(a) contains only four levels. The four segments S_1, S_3, S_4 , and S_5 correspond to the four maxima located within the most white part of the image. Segment S_2 and its subsegments S_6

Figure 9. Hierarchy tree of Fig. 4(a). Segments are labelled corresponding to Fig. 8. Segments $S_2, \dots, S_5$ are subsegments of segment S_1 , but annihilate in the sequence S_4, S_5, S_3, S_2 at increasing scale.

and S_7 correspond to the three minima in the interior. The hierarchical structure of this image is shown in Fig. 12. To visualise the role of Segment S_1 compared to the other maxima—the part of the tree with

catastrophes 2, 3, and 4—the critical intensity of segment S_3 (the adjoined segment by catastrophe 2) was assigned to it. The pre-segmentation with this extra segment is shown in Fig. 11(c).

As an (other) example of a tree operation on Fig. 12, recall that the four segments S_1, S_3, S_4 , and S_5 correspond to the four maxima located within the most white part of Fig. 11(a). We can therefore simplify the tree by clustering these four segments to one region of interest, ‘the bright region’. The iso-intensity manifolds have the intensity of the scale space saddle defining segment S_3 . Similarly, Segment S_2 and its subsegments S_6 and S_7 correspond to the three minima in the interior of Fig. 11(a), the dark region in the middle, and can be clustered to one region, ‘the dark region’.

The part in scale space bounded by the intensity of the scale space saddles is found by a 3D region growing algorithm. The intersection of the simplified bright and dark region with the initial MR image, Fig. 4(b), are shown in Fig. 13(a) and (b). The pre-segmentation of the initial image with respect to these two parts together with the segments S_0 and S_1 is shown in Fig. 13(c).

With the simulated MRI (again shown in Fig. 14(a)), also the probabilistic distributions of the white matter (Fig. 14(b)) and the gray matter (Fig. 14(c)) are given as ground-truth images with values ranging from 0 to 255.

Comparing Figs. 13(a) and 14(b) shown that the intensity defining the scale space segment of the bright region is a good estimator of the threshold value to the white matter. However, this region is connected whereas the white matter distribution also contains isolated regions. To overcome this difference, we compare the given distributions the initial image thresholded on the values of the scale space saddles.

Figure 14(d) shows a direct intersection of the original image, Fig. 14(a), with all the iso-intensity manifolds equalling the intensities of the 7 extrema of

Figure 10. Parametrised intensities of the critical points of the scale space of Fig. 11(a); 89 scales exponentially sampled from 8.37 to 33.1. Left: All 15 critical points. Right: Intensities of the six spatial saddles.

Figure 12. Hierarchy of Fig. 11(a).

the parametrised critical curves. So the range of values is reduced from $0, \dots, 255$ in the initial image to $0, \dots, 8$.

The original image thresholded on the intensity defining segment S_3 is shown in Fig. 14(e). The difference with Fig. 13(a) yields four isolated regions, three in the middle and one in the bottom-right part of the image.

Furthermore, the gray matter can be estimated by subtraction of the bright and the dark regions, as Fig. 13(c) indicates. The original image thresholded

on the values of these bright and dark regions is shown in Fig. 14(f).

To compare the Fig. 14(b) and (c) with the Fig. 14(e) and (f) we used the similarity measure of two segments A and B defined by $2 \frac{A \cap B}{A + B}$. Since the Fig. 14(b) and (c) are probabilistic segmentations, they are made binary by thresholding them on the value 128. Then the similarity of the Fig. 14(b) and (e) is 96.6% and of the Fig. 14(c) and (f) is 68.1%. The similarity of the unions of Fig. 14(b) + (c) and of Fig. 14(e) + (f) is 89.9%. The error is mainly caused by pixels included only in the segmentation of the ground truth. In other words, Fig. 14(e) and (f) give an underestimation of the probabilistic distributions. The regions found by the tree simplification may be used as an initialisation of a post-processing step to obtain a more accurate segmentation based on the geometry of the image. The latter is obviously not present in the hierarchy tree.

5. Conclusions and Discussion

We developed a method to calculate the hierarchical structure of an arbitrary input image. The method is

Figure 13. Intersection of the initial image, Fig. 4(a), with various scale space parts (see text). (a) The bright region. (b) The dark region. (c) Hierarchy simplified to four parts.

Figure 14. Top row: (a) Simulated MR brain image, Fig. 4(b). (b) Ground-truth distribution of white matter. (c) Ground-truth distribution of grey matter. based on the scale space image of the input image and the critical paths within it. The latter exist of branches of spatial extrema and spatial saddle points. The range of scales at which these branches exist follow from their catastrophe points in scale space. These points essentially describe annihilations or creations of pairs of spatial critical points. To each spatial extremum an iso-intensity manifold is assigned. The value of this manifold equals that of the global intensity extremum of the saddle branch that is connected by the annihilation with the extremum branch containing the spatial extremum. This global intensity extremum is located at either the initial scale or at a scale space saddle, a critical point in scale space. The iso-intensity manifold encapsulates the extremum in scale space. The manifolds through the extrema are nested and non-intersecting and thus form a hierarchy.

In contrast to what has been described in the literature we showed that these manifolds necessarily should be chosen such that they go through the scale space saddle instead of the annihilation point.

As application, this structure can be visualised as a pre-segmentation by the intersection of the iso-intensity manifolds with the image at a specified scale or with the input image. The word “pre-segmentation”

is chosen, since it is not a task-specified segmentation, but only a division of the image in several topologically defined parts without any a priori knowledge about the contents of the image itself. It may be thus used as an initial segmentation for further post-processing. Other applications may include e.g. clustering and data compression.

The proposed algorithm has two main advantages. Firstly, it has a severe mathematical underpinning which encourages and facilitates future improvements, and admits reproducible, predictable, and provable segmentation results. Secondly, it has the potential to include semantics enabling an intelligent choice of the nodes, either by deterministic, statistic or probabilistic means.

Experimental results based on artificial images and simulated MRI with respect to the hierarchy and pre-segmentation were given. They clarified the theory and showed results that correspond to a fair size to both the mathematical and the intuitive forecast.

A. Appendix

We clarify the theory presented in Section 2 by discussing the appearance of scale space saddles at

Figure 15. (a) Parametrised intensity of a fold catastrophe in 1D with respect to scale. (b) $(x, t, L(x; t))$ scale space surface of the fold catastrophe with iso-intensity curves $L(x; t) = c$. (c) Segments of (b), defined by the scale space saddle intensity $L(x; t) = 0$: for $t < 0$ four segments exist, for $t > 0$ two remain.

the generic catastrophe event in scale space describing an annihilation. This event, called a Fold catastrophe, is known from catastrophe theory (see e.g. [1, 2, 5, 13, 14, 42, 48, 52, 53]) and applied to and used in scale space (see e.g. [8–10, 12, 22–26, 34]). Firstly, an example on one-dimensional images is given, because scale space saddles coincide with the catastrophe points. Secondly, the results on a multi-dimensional image is discussed.

A.1. 1D Images

In 1D images the iso-intensity manifolds (or separatrices) are given by the isophotes through the catastrophes points, since these points are identical to the scale space saddles: $H = L_{xx}$ and $L_t = \Delta L = L_{xx}$. The extended Hessian, Eq. (4), reads

$$\mathcal{H} = \begin{pmatrix} 0 & L_{xxx} \\ L_{xxx} & L_{xxxx} \end{pmatrix}.$$

It is generically non-zero at scale space saddles and $\det \mathcal{H} = -L_{xxx}^2 < 0$. The generic annihilation is described by

$$L(x; t) = x^3 + 6xt$$

and has a scale space saddle if both derivatives are zero, that is, $L_x = 3x^2 + 6t = 0$ and $L_t = 6x = 0$. So it is located at the origin with intensity equal to zero. The parametrisation of the critical curve with respect to the scale t is $(x(s); t(s)) = (\pm\sqrt{-2s}; s)$, $s \leq 0$ and the parametrised intensity reads $P(s) = \pm 4s\sqrt{-2s}$, $s \leq 0$, see Fig. 15(a). This parametrisation has its local extremum at $s=0$, the right boundary of the interval on which the branches are defined. An alternative parametrisation of the critical curve, based on the position of the critical points, reads $(x(s); t(s)) =$

$(s; -\frac{1}{2}s^2)$, $\forall s$. Then $P_1(s) = -2s^3$ and its critical point $s = 0$ is a point of inflection.

The dome defined by the scale space saddle is given by the isophotes $L(x; t) = 0$ through the origin, so $(x; t) = (0; t)$ and $(x; t) = (x; -\frac{1}{6}x^2)$. Figure 15(b) shows isophotes in the $(x, t, L(x; t))$ -space, where the isophote $L = 0$ gives the annihilation point with the separatrices. The separation curves in the $(x; t)$ -plane are shown in Fig. 15(c).

At the catastrophe point the isophotes of the scale space saddle form a pitchfork. Due to the causality principle it has 3 branches downwards and only one upward, i.e. at the scale space saddle four separate regions change to two separate regions. Locally the isophotes are described by $L(x; t) = L_{xt}(\frac{1}{6}x^3 + xt) \stackrel{\text{def}}{=} 0$, so the horizontal traversing branches of the scale space saddle isophote necessarily have negatively oriented branches by $t = -\frac{1}{6}x^2$.

A.2. n-D Images, $n > 1$

In higher dimensions the structure is more complicated, since the scale space saddle does not coincide with the catastrophe point. For n -D images, $n > 1$, it suffices to investigate scale space critical points in 2D, see e.g. [8–10, 14, 48, 52, 53].

If we assume $L_{yy} = -L_{xx}$ as to satisfy $\Delta L = 0$, the extended Hessian, Eq. (4), becomes

$$\mathcal{H} = \begin{pmatrix} L_{xx} & L_{xy} & L_{xt} \\ L_{xy} & -L_{xx} & L_{yt} \\ L_{xt} & L_{yt} & L_{tt} \end{pmatrix}.$$

The determinant is $-L_{tt}(L_{xx}^2 + L_{xy}^2) + L_{xx}(L_{xt}^2 - L_{yt}^2) + 2L_{xt}L_{xy}L_{yt}$ and the trace simplifies to L_{tt} , which are both generically non-zero.

Figure 16. 2D Surface trough a scale space saddle; see text for further details.

The annihilation germ reads

$$L(x, y; t) = x^3 + 6xt + \alpha(y^2 + 2t), \quad (6)$$

where $\alpha = \pm 1$. Positive sign describes a saddle—minimum annihilation, negative sign a saddle—maximum one. Without loss of generality we take $\alpha = 1$. Then $L_x = 3x^2 + 6t$, $L_y = 2y$, $L_t = 6x + 2$, and $\det(H) = 12x$, so the catastrophe takes place at the origin with intensity equal to zero and the scale space saddle is located at $(x, y; t) = (-\frac{1}{3}, 0; -\frac{1}{18})$ with intensity $-\frac{1}{27}$. The surface $L(x, y; t) = -\frac{1}{27}$ is shown in Fig. 16. It has a local maximum at $(x, y; t) = (\frac{1}{6}, 0; -\frac{1}{12})$: the top of the extremum dome.

The iso-intensity surface through the scale space saddle can be visualised by two surfaces touching each other at the scale space saddle. One part of the surface is related to the corresponding extremum of the saddle. The other part encircles another—currently unknown—segment of the image. The surface belonging to the extremum forms a dome. The critical curve intersects this surface twice. The saddle branch has an

intersection at the scale space saddle, the extremum branch at the top of the dome.

The parametrisation of the critical curve with respect to t (that is: a parametrisation of the branches of the critical curve) is given by $(x(s), y(s); t(s)) = (\pm\sqrt{-2s}, 0; s)$, $s \leq 0$.

The intensity of the critical curve (shown in Fig. 17(a)) then reads $P(s) = 2s \pm 4s\sqrt{-2s}$, $s \leq 0$, with $\partial_s t(s) = 1$ and $\partial_s P(s) = 2 \pm 6\sqrt{-2s} = \Delta L \cdot t_s(s)$. The critical points of $P(s)$ are given by the scale space saddle, located at $s = -\frac{1}{18}$, and the catastrophe, located at $s = 0$, the boundary of the interval on which the branches are defined. These points are visible in Fig. 17(a) as the local minimum of the parametrisation curve and the connection point of the two curves (a local maximum). The upper branch represents the spatial saddle, the lower one the minimum.

This image led Lifshitz and Pizer [37] to the observation that the intensity of the saddle point decreased even below the annihilation intensity resulting in theoretically problematic linking due to the escape of non-extremum paths from the extremal region they originate in.

This is, however, a generic property of scale space images and shows in an elegant way the necessity of limiting the extremal region by the critical iso-intensity manifold formed by the scale space saddle intensity.

An alternative parametrisation of the critical curve is given by $s = x$, so $(x(s), y(s); t(s)) = (s, 0; -\frac{1}{2}s^2)$, that is: a parametrisation of both branches of the critical curve simultaneously, based on the spatial position of the critical points. Then the intensity of the critical curve is given by $P_1(s) = -2s^3 - s^2$. Now $\partial_s t(s) = -s$ and $\partial_s P_1(s) = -6s^2 - 2s = (6s + 2)(-s)$ and the latter is still equivalent to $\Delta L \cdot t_s(s)$. The critical points of $P_1(s)$ are given by $s = 0$, the catastrophe point, and at $s = -\frac{1}{3}$, the scale space saddle. These points are

Figure 17. Intensity of the critical curve at fold catastrophe in 2D, parametrised by (a) the t -coordinate and (b) the x -coordinate. Both show at the origin an annihilation, at the minimum the scale space saddle.

visible in Fig. 17(b) as the extrema of the parametrisation curve. The branch $s < 0$ represents the saddle point, the branch $s > 0$ the minimum.

Note

1. Notation due to Gilmore [14]. Also the terminology *normal forms* is used in the literature, e.g. by Poston and Stewart [48].

Arjan Kuijper received his M.Sc. degree in applied mathematics in 1995 with a thesis on the comparison of two image restoration techniques, from the University of Twente, The Netherlands. During the period 1996–1997 he worked at ELTRA Parkeergroep, Ede, The Netherlands. In the period 1997–2002 he has been a Ph.D. student and associate researcher at the Institute of Information and Computing Sciences of Utrecht University. In 2002 he received his Ph.D. degree with a thesis on "Deep Structure of Gaussian Scale Space Images". Currently he is postdoc at Utrecht University on the project "Co-registration of 3D Images" on a grant of the Netherlands Ministry of Economic Affairs within the framework of the Innovation

Oriented Research Programme. His interest subtends all mathematical aspects of image analysis, notably multiscale representations, catastrophe and singularity theory and applications to medical imaging.

Luc M.J. Florack received his M.Sc. degree in theoretical physics in 1989, and his Ph.D. degree in 1993 with a thesis on image structure, both from Utrecht University, The Netherlands. During the period 1994–1995 he was an ERCIM/HCM research fellow at INRIA Sophia-Antipolis, France, and INESC Aveiro, Portugal. In 1996 he was an assistant research professor at DIKU, Copenhagen, Denmark, on a grant from the Danish Research Council. From 1997 until June 2001 he was an assistant research professor at Utrecht University at the Department of Mathematics and Computer Science. Since June 1st 2001 he has been working as an assistant research professor—and about to be appointed associate research professor—at Eindhoven University of Technology, Department of Biomedical Engineering. His interest subtends all structural aspects of signals, images and movies, notably multiscale representations, and their applications to imaging and vision.

Max A. Viergever received the M.Sc. degree in applied mathematics in 1972 and the D.Sc. degree with a thesis on cochlear mechanics in 1980, both from Delft University of Technology. From 1972 to 1988 he was Assistant/Associate Professor of Applied Mathematics at this university. Since 1988 he has been Professor and Head of the Department of Medical Imaging at Utrecht University, since 1996 Adjunct Professor of Computer Science at the same university, since 1996 Scientific Director of the Image Sciences Institute of the University Medical Center Utrecht, and as of 1998 Director of the Graduate School of Biomedical Image Sciences (ImagO). He is (co)author of over 300 refereed scientific articles (abstracts excluded) on biophysics and medical image processing, guest editor of seven journal issues, (co)author/editor of 15 books, and has served as supervisor of 80 M.Sc. students and 45 Ph.D. students. His research interests comprise all aspects of computer vision and medical imaging. Max Viergever is a board member of IAPR, IPMI and MICCAI, is editor of the book series Computational Imaging and Vision of Kluwer Academic Publishers, associate editor-in-chief of the IEEE Transactions on Medical Imaging, editor of the Journal of Mathematical Imaging and Vision, and has acted as associate editor, guest editor or editorial board member of nine more international journals.
