Error Probability Analysis of Bit-Interleaved Coded Modulation
Alfonso Martinez, Member, IEEE,
Albert Guillén i Fàbregas, Member, IEEE, and
Giuseppe Caire, Fellow, IEEE

Abstract—This correspondence presents a simple method to accurately compute the error probability of bit-interleaved coded modulation (BICM). Thanks to the binary-input output-symmetric (BIOS) nature of the channel, the pairwise error probability (PEP) is equal to the tail probability of a sum of random variables with a particular distribution. This probability is in turn computed with a saddlepoint approximation. Its precision is numerically validated for coded transmission over standard Gaussian noise and fully interleaved fading channels for both convolutional and turbo-like codes.

Index Terms—Additive white Gaussian noise (AWGN) channel, bit-interleaved coded modulation (BICM), error probability, saddlepoint approximation, Gaussian approximation, fading channel.

I. INTRODUCTION

Bit-interleaved coded modulation (BICM) was introduced by Zehavi [1] as a pragmatic coding scheme for spectrally efficient modulations. Under the assumption of sufficient bit interleaving at the encoder output, it was later extensively studied by Caire et al. [2], who suggested that the system essentially behaves as a memoryless binary-input output-symmetric (BIOS) channel. This consideration allows for an easy calculation of channel capacity (average mutual information) and cutoff rate for arbitrary modulation alphabets and symbol labelings. However, the analysis of error probabilities in [2] was either not tight or exceedingly complex to compute. In this correspondence, we elaborate on their methods and obtain a simple and very accurate method to estimate the error probability.

II. ERROR PROBABILITY ANALYSIS

A. Channel Model

We study coded modulation over Gaussian noise channels. The discrete-time received signal can be expressed as

\[ y_k = \sqrt{SNR} h_k x_k + z_k, \quad k = 1, \ldots, L \]  \hspace{1cm} (1)

where \( y_k \) is the (complex-valued, i.e., \( y_k \in \mathbb{C} \)) \( k \)th received sample, \( h_k \in \mathbb{C} \) is the \( k \)th fading attenuation, \( x_k \in \mathbb{C} \) is the transmitted signal.

Manuscript received November 30, 2004; revised August 1, 2005. This work was supported in part by the ANTIPODE project of the French Telecommunications Research Council RNRT, and by Institut Eurécom’s industrial partners: Bouygues Télécom, Fondation d’Entreprise Groupe Cégetel, Fondation Hasler, France Télécom, Hitachi, STMicroworlds, Swisscom, Texas Instruments, and Thales. The material in this correspondence was presented in part at the 2004 Conference on Information Sciences and Systems, Princeton University, Princeton, NJ, March 2004, and at the 2004 International Symposium on Information Theory and Its Applications, Parma, Italy, October 2004.

at time \( k \), and \( z_k \in \mathbb{C} \) is the \( k \)th noise sample, assumed to be complex Gaussian independent and identically distributed (i.i.d.) \( \sim \mathcal{CN}(0, 1) \). BICM codewords \( \mathbf{x} = (x_1, \ldots, x_L) \) are obtained by bit interleaving the codewords \( \mathbf{c} = (c_1, \ldots, c_N) \) of the code \( C \), each of dimension \( K \) information bits and length \( N \), and mapping over the signal constellation \( \mathcal{X} \) with the labeling rule \( \mathbf{\mu} : \{0, 1\}^N \rightarrow \mathcal{X}, M = \log_2 |\mathcal{X}| \). The corresponding transmission rate is \( R = \frac{K}{N} \) bits per channel use. The average received signal-to-noise ratio is SNR. We denote the vector of received symbols by \( \mathbf{y} = (y_1, \ldots, y_L) \). The standard additive white Gaussian noise (AWGN) and fully interleaved Rayleigh-fading channels are obtained from (1) by simply letting \( h_k = 1 \) and \( h_k \sim \mathcal{CN}(0, 1) \), respectively. The operation is depicted in Fig. 1.

B. Error Probability Under ML Decoding

For maximum-likelihood (ML) decoding, the error probability of linear binary codes over BIOS channels is accurately given by the union bound in the region above the cutoff rate [3]. Let \( \Lambda_d \) denote the number of codewords in \( C \) with Hamming weight \( d \). In the region above the cutoff rate, the codeword error probability is very closely upper-bounded by

\[ P_e \leq \sum_d \Lambda_d \text{PEP}(d, \mu, \mathcal{X}, \text{SNR}) \]  \hspace{1cm} (2)

where \( \text{PEP}(d, \mu, \mathcal{X}, \text{SNR}) \) is the pairwise error probability (PEP) for two codewords differing in \( d \) bits.\(^2\) Estimating the error probability reduces therefore to computing the PEP. Assuming that codeword \( \mathbf{c} \) was transmitted, the probability of choosing a candidate codeword \( \mathbf{c}' \) at Hamming distance \( d \) from \( \mathbf{c} \) is given by

\[ \text{PEP}(d, \mu, \mathcal{X}, \text{SNR}) = \Pr( \{\hat{c}' \mid y \} > \{\hat{c} \mid y \} | \mathbf{c} = c) \]
\[ = \Pr \left( \sum_i \log \frac{\Pr(\hat{c}_i = \hat{c}_i | y) \mid \mathbf{c} = c)}{\Pr(\hat{c}_i = \hat{c}_i | y) \mid \mathbf{c} = c} > 0 \mid \mathbf{c} = c \right) \]

where we have used that the \( i \)th bit depends only its corresponding channel output \( y_{k(i)} \). The random elements in the channel output include the noise and fading realizations \( z \) and \( h \), respectively, the particular modulation symbol \( x \), and the bit position in the binary label \( m \). In order to avoid cumbersome notation, we group them in a vector \( \mathbf{V} \triangleq (z, h, x, m) \); \( \mathbf{V} \) depends on the modulation alphabet \( \mathcal{X} \), the labeling \( \mu \), and SNR. Taking into account that only the bit positions for which \( \hat{c}_i \neq \hat{c}_i \) must be considered, the PEP is given by

\[ \text{PEP}(d, \mu, \mathcal{X}, \text{SNR}) = \Pr \left( \sum_{i=1}^{d} \Lambda_j > 0 \right) \]  \hspace{1cm} (3)

where we have defined a new random variable, denoted by \( \Lambda \), the \( \text{a posteriori} \) log-likelihood ratio, as

\[ \Lambda = \log \frac{\Pr(\hat{c} = c | \mathbf{V})}{\Pr(\hat{c} = \bar{c} | \mathbf{V})} \]  \hspace{1cm} (4)

Thanks to the presence of the interleaver [2], the variables \( \Lambda \) can be considered, to a practical extent, i.i.d. Furthermore, due to the sym-

\(^2\)We assume perfect channel state information (CSI) at the receiver. However, the extension of technique described here to the nonperfect CSI case is straightforward.

\(^3\)Similarly, the bit-error probability \( P_{b_k} \) is given by the right-hand side of (2) with \( \Lambda_d \) replaced by \( \Lambda_d = \sum_{j=0}^{d} \Lambda_j \), \( \Lambda_d \) being the number of codewords in \( C \) with output Hamming weight \( d \) and input weight \( i \).
seems difficult to obtain, it is nevertheless simple to evaluate it by
computable distribution. For example, for the binary-symmetric channel
symmetry of the channel output, their distribution does not depend on the
value of \( c \), and we can safely assume that the all-zero codeword has
been transmitted.

It should be noted that this formulation is simply a restatement of the
results in [2] with a different notation. In particular, the exact
dependence of the error probability on the modulation symbol or the bit
index is dropped, or rather considered another random variable similar
to the noise or fading realizations. Fig. 1 shows the location of \( \Lambda \) in
the communication channel, after the demodulator.

The \textit{a posteriori} probabilities used in the computation of \( \Lambda \) are given by

\[
\Pr(\hat{c} = c | \mathcal{V}) \triangleq \Pr(\hat{c} = c | z, h, x, m) \propto \sum_{c \in \mathcal{X}^m_{n}} \exp(-|y - \sqrt{SNR}h,c|^{2})
\]

where \( \mathcal{X}^m_{n} \) is the subset of signal constellation points with \( m \) binary
label position equal to \( c \).

In [2], three alternative methods were given to compute \( \text{PEP}(d, \mu, X, \text{SNR}) \): the Bhattacharyya-union bound (B-UB),
the BICM bound, and the expurgated BICM union bound (ex-UB). Of
these, the B-UB will be analyzed later. The BICM bound was used as
a means to derive the tighter expurgated bound and, therefore, we do
not analyze it further. It is interesting to note that a careful examination
of the expression for the expurgated bound in [2] reveals that it is
equal to (4) restricting the sum in (5) to one single term, the nearest
neighbor. Proceeding directly from the assumption of a memoryless
BIOS channel, their derivation can be significantly shortened. Further-
more, for non-Gray labeling, the effect of the other neighbors is not
negligible, and thus the ex-UB may not be accurate [2].

C. Log-Likelihood Ratio Distribution

For some BIOS channels, the ratio \( \Lambda \) has a known and easily
manageable distribution. For example, for the binary-symmetric channel
(BSC) \( \Lambda \) is a binomial random variable. For the binary-input AWGN
channel with signal-to-noise ratio \( \text{SNR} \), \( \Lambda \) is normally distributed
\( \mathcal{N}(-1 \text{SNR}, 8 \text{SNR}) \). A little algebra shows that for binary-input
Rayleigh-fading channels, the density is two-sided exponential

\[
f_{\Lambda}(\Lambda) = \frac{1}{4 \sqrt{\text{SNR}(1 + \text{SNR})}} \times \exp\left(-\frac{\Lambda}{2} \left(1 + \text{sign}(\Lambda) \sqrt{\frac{1 + \text{SNR}}{\text{SNR}}} \right) \right).
\]

Even though a closed-form expression for the density of \( \Lambda \) for BICM
seems difficult to obtain, it is nevertheless simple to evaluate it by
computer simulation if required.

In estimates of tail probabilities, the cumulant transform \( \kappa(s) \) (or
cumulant generating function) of a random variable \( \Lambda \) is a more con-
venient representation than the density. The transform is given by

\[
\kappa(s) \triangleq \log \mathbb{E}[e^{s\Lambda}]
\]

with \( s \in \mathbb{C} \) [4]. Using the definition of \( \Lambda \), we rewrite \( \kappa(s) \) as

\[
\kappa(s) \equiv \log \mathbb{E}_{\mathcal{V}} \left[ \frac{\Pr(\hat{c} = 1 | \mathcal{V})}{\Pr(\hat{c} = 0 | \mathcal{V})} \right]^{d}
\]

where the subscript \( \mathcal{V} \) indicates that the expectation is taken with re-
pect to all nuisance parameters \( \mathcal{V} = (z, x, h, m) \). This expectation
can be easily evaluated by numerical integration using the Gauss–Her-
mite (for the AWGN channel) and a combination of the Gauss–Her-
mite and Gauss–Laguerre (for the fading channel) quadrature rules, which
are tabulated in [5].

It will also prove convenient to define the saddlepoint \( \hat{s} \) as the value
for which \( \kappa'(\hat{s}) = 0 \). It can be shown that this point exists and is
unique [6]. For BIOS channels, symmetry dictates that the saddlepoint
is placed at \( \hat{s} = 1/2 \), with no need to carry an explicit numerical min-
imization step [7].

Fig. 2 shows the computer-simulated density of \( \Lambda \) for 16-QAM over
an AWGN channel and 8-PSK over a Rayleigh-fading channel with
\( \text{SNR} = 12 \text{ dB} \) and \( \text{SNR} = 7 \text{ dB} \), respectively. In both cases, the
labeling is Gray. For the sake of comparison, Fig. 2 also shows the distri-
bution of a Gaussian random variable with distribution \( \mathcal{N}(-4\gamma, 8\gamma) \),
with \( \gamma = -\kappa(\hat{s}) \). It should be noted that this Gaussian approximation
is valid in the tail of the distribution, rather at the mean as would be
the case for the standard Gaussian approximation \( \mathcal{N}(\mathbb{E}[\Lambda], \mathbb{E}[\Lambda^{2}] -
\mathbb{E}[\Lambda^{2}]) \). It is remarkable how close the tails are to the tail of a Gaussian
random variable for the case of AWGN. For the Rayleigh fading, the
density inherits the exponential behavior of the binary-input case, and
the Gaussian approximation to the tail is somewhat less accurate.

D. Gaussian Approximation

The preceding discussion suggests approximating the PEP by

\[
\text{PEP}(d, \mu, X, \text{SNR}) \approx Q(\sqrt{-2d\kappa(\hat{s})})
\]

a result which was heuristically introduced in [8]. The approximation
in (9) corresponds as well to the zeroth-order term in the Lugannani–Rice
formula [9] (see also [10]).

E. Bhattacharyya Union Bound

The Bhattacharyya bound [7] can be used to upperbound the PEP as

\[
\text{PEP}(d, \mu, X, \text{SNR}) \leq e^{d\kappa(\hat{s})}
\]

\[
= \mathbb{E}_{\mathcal{V}} \left[ \frac{\Pr(\hat{c} = 1 | \mathcal{V})}{\Pr(\hat{c} = 0 | \mathcal{V})} \right]^{d}
\]

Notice that this coincides with the Chernoff bound as \( \hat{s} = 1/2 \). Using
this in (2) we obtain the B-UB proposed in [2].
F. Saddlepoint Approximation

In the Appendix I, we present the derivation of the saddlepoint approximation and of an estimate of the approximation error to the PEP. Even though the derivation in the Appendix is uniformly valid for all values of the saddlepoint \( \hat{s} \), including small values of \( \hat{s} \), in our case this is not required as \( \hat{s} = 1/2 \). Keeping only the first-order term in the asymptotic series, the PEP can be approximated by

\[
\text{PEP}(d, \mu, \lambda, \text{SNR}) = \frac{1}{\sqrt{2\pi d k''(\hat{s})}} e^{d(\hat{s})} \left[ 1 + O(dk''(\hat{s}))^{-1} \right]
\]

(12)

where the term \( O(dk''(\hat{s}))^{-1} \) decays fast as a power of \( (dk''(\hat{s}))^{-1} \). The effect of the correction is found to be negligible in practical calculations, which implies that we need not sum over any more terms in the asymptotic series and we may then drop the \( O(\cdot) \) term.

The exponent is the same as for the Bhattacharyya bound, in accordance to the asymptotic optimality of the latter, and coincides as well with the exponential decay of the Gaussian approximation. Note that efficient computation of the second derivative \( k''(\hat{s}) \)

\[
k''(\hat{s}) = \frac{E[\hat{X}^2 e^{\hat{X}^2 \lambda}]}{E[e^{\hat{X}^2 \lambda}]}
\]

\[
= \frac{1}{E[e^{\hat{X}^2 \lambda}]} E\left[ \left( \frac{\log \Pr(\hat{c} = 1 | V)}{\Pr(\hat{c} = 0 | V)} \right)^2 \frac{\Pr(\hat{c} = 1 | V)}{\Pr(\hat{c} = 0 | V)} \right]
\]

(13)

can again be performed using Gaussian quadrature rules.

It is worthwhile remarking that the method advocated in [2] to compute this probability for the expurgated union bound (UB) was the use of integration in the complex plane. It can be seen that the saddlepoint method is an alternative to the complex-plane integration. Instead of directly computing the integral, its value is very accurately approximated with a method of significantly lower complexity.

III. NUMERICAL RESULTS AND DISCUSSION

In this section, we show some numerical results that illustrate the accuracy of the proposed methods as well as its asymptotic behavior. In particular, we show the following: the B-UB, the saddlepoint approximation (12) union bound (SP-UB), the Gaussian approximation tangential-sphere bound (GA-TSB) [8],5 and the simulation of the bit-error rate (BER sim). For every block of information bits a different bit interleaver is randomly generated.

A. AWGN Channel

Figs. 3 and 4 show the bit-error probability as a function of \( E_b / N_0 = \text{SNR} / \beta \) for the aforementioned methods and for convolutional and repeat–accumulate (RA) codes with 16-QAM in the AWGN channel with no fading. In Fig. 3, we use the optimum 64-state and rate-1/2 convolutional code with Gray and set partitioning mappings and in Fig. 4 an RA code [12] of rate 1/4 with Gray mapping.

The performance at medium-to-high signal-to-noise ratio is very well approximated by both the Gaussian and the saddlepoint approximations, for all considered labelings and codes. Note that the performance estimate in the case of set-partitioning labeling remarkably improves the bound presented in [2]. In essence, this can be traced back to the accuracy of the Gaussian approximation to the tail of the log-likelihood ratios \( \lambda \), already discussed in Section II-C. The B-UB yields the correct decay of the bit error curve but it remains at a fixed gap from the true bit error probability. The accuracy of

5This is the standard tangential sphere bound [11] for a binary-input AWGN channel with \( \text{SNR} = \lambda \).

Fig. 2. Density of the a posteriori log-likelihood ratio \( \lambda \): empirical distribution (solid line, computer simulated) and Gaussian approximation to the tail (dash-dotted) for 16-QAM/8-PSK, Gray mapping, and AWGN/Rayleigh fading.
the union bound-based approximations for the RA code ensemble appears only in the error floor region, since the union bound is not tight for random-like codes for SNR below the corresponding cutoff rate. Nevertheless, the GA-TSB yields a fairly good estimate of the waterfall behavior of the error curve also for low SNR.

In all cases, the decay of the bit error for increasing signal-to-noise ratio seems to be of exponential nature. Appendix III proves the asymptotic validity of this conjecture and shows that

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(\Delta)}{\text{SNR}} = -\frac{d_{\min}^2}{4}
\]

where \(d_{\min}\) is the minimum Euclidean distance of the constellation. As outlined in the proof, at large SNR, BICM behaves as a binary modulation with distance \(d_{\min}\), regardless of the mapping. This result confirms that BICM preserves the properties of the underlying binary code and that for large SNR the error probability decays exponentially with SNR as \(e^{-\frac{1}{2}d_{\min}^2 \Delta^2}\). In this line, Fig. 5 shows \(\frac{\kappa(\Delta)}{\text{SNR}}\) for 16-QAM with Gray and set partitioning mappings in the AWGN channel. The asymptotic value is \(\frac{\kappa(\Delta)}{\text{SNR}} = 0.1\), as established by the preceding result.

In the Gaussian approximation, the quantity \(\frac{\kappa(\Delta)}{\text{SNR}}\) can be interpreted as the SNR scaling with respect to SNR when using BICM [8] and
thus, the asymptotic scaling depends only on the signal constellation $\mathcal{X}$ (through its minimum distance) and not on the labeling $\mu$.

As shown in Appendix I, the second-order cumulant evaluated at the saddlepoint $\kappa''(\tilde{s})$ plays an important role in assessing the error of the approximation. Appendix III also shows that

$$\lim_{\text{SNR} \to \infty} \frac{\kappa'(\tilde{s})}{\text{SNR}} = 2\kappa_{\text{min}}^2.$$  \hspace{1cm} (15)

Fig. 5 also shows $\kappa''(\tilde{s})/\text{SNR}$ for 16-QAM with Gray and set partitioning mappings in the AWGN channel. The limit coincides with the above result, and implies that, in the AWGN channel, the saddlepoint approximation becomes more and more accurate as SNR grows.

### B. Fully Interleaved Rayleigh Fading Channel

Figs. 6 and 7 show the estimates of the bit error probability for convolutional and RA codes, respectively, in a fully interleaved AWGN channel with Rayleigh fading. Fig. 6 shows two cases, a rate-$2/3$, 8-state optimum code over 8-PSK, and the rate-$1/2$, 64-state optimum code over 16-QAM both with Gray mapping. Fig. 7 shows the performance of an RA code of rate $1/4$ with Gray mapping and 16-QAM modulation.

Similarly to the AWGN case, the three approximations to the error rate give the correct slope of the decay with SNR at medium-to-high signal-to-noise ratio, while the horizontal shift of the curves is different. All approximations are close to the simulated value, but now only the saddlepoint approximation gives an accurate estimate. As we saw in Section II-C, the tail of the log-likelihood ratio $\Lambda$ in the fading channel is approximately exponential, rather than Gaussian, and this shape is not correctly tracked by the Gaussian approximation. On the contrary, the saddlepoint approximation is able to "learn" the shape of the variable. As evidenced by the results of 16-QAM with the 64-state convolutional code, this effect becomes less apparent for more powerful codes with large minimum distance, since the sum in (3) contains more terms and its tail is closer to a Gaussian. Again, the GA-TSB yields the most accurate estimate of the error probability in the low-SNR region. The accuracy of the UB-based approximations for the RA code ensemble is accurate in the error floor region.

Note also that BICM preserves the properties of the underlying binary code for fully interleaved Rayleigh-fading channels as well, as the error probability decays as an inverse power of SNR. Appendix III shows that in the limit for large SNR the rate of decay varies as

$$\lim_{\text{SNR} \to \infty} \frac{\kappa(\tilde{s})}{\log \text{SNR}} = -1$$

and that

$$\lim_{\text{SNR} \to \infty} \kappa''(\tilde{s}) = 8$$

confirming that BICM indeed behaves as a binary modulation and thus, the asymptotic performance depends on the Hamming distance of the code rather than on the Euclidean distance. Fig. 5 also shows $\kappa''(\tilde{s})$ as a function of SNR for 16-QAM and 8-PSK with Gray mapping in the fully interleaved Rayleigh-fading channel. As expected, the limit value is 8, and does not depend on the modulation.

### IV. Conclusion

In this correspondence, we have presented a simple method to compute a tight approximation to the error probability of BICM. This probability is found to correspond in a natural way to the tail probability of a sum of independent random variables, which is calculated using the saddlepoint approximation. The exact form of the approximation
Fig. 6. Comparison of simulation and saddlepoint and Gaussian approximations on the bit error rate of BICM with a 8-state, rate-2/3 convolutional code with 8-PSK modulation and a 64-state, rate-1/2 convolutional code with 16-QAM, both with Gray mapping.

Fig. 7. Comparison of simulation and saddlepoint and Gaussian approximations on the bit error rate of BICM with a Repeat-and-Accumulate code of rate 1/4 with 16-QAM modulation and Gray mapping, $K = 512$ information bits, 20 iterations of belief propagation decoding the fully-interleaved Rayleigh fading channel.

is new since, as opposed to the usual formulas, it is uniformly valid for all values of the saddlepoint. The proposed method benefits from simple numerical integration using Gaussian quadratures for noise and fading averaging. We have verified the validity of the approximation for both, convolutional and turbo-like code ensembles with BICM, over AWGN and fully interleaved Rayleigh-fading channels. In both cases, the asymptotic behavior of BICM mimics that of binary modulation. This simple technique constitutes a powerful tool to the analysis of finite-length BICM. Furthermore, being simpler and tighter than the original bounds in [2], it shows a wide range of practical applications.
APPENDIX I
DERIVATION OF THE SADDLEPOINT APPROXIMATION

We wish to estimate the tail probability of $Z$, a continuous random variable with density $f_Z(z)$. To $Z$ we associate its cumulant transform (or cumulant generating function) $\kappa(s)$, defined as

$$\kappa(s) = \log E[e^{sz}], s \in \mathbb{C}.$$ We shall be concerned with the case of $Z$ being the sum of $M$ random variables $X_i, Z = \sum_{i=1}^{M} X_i$. For independent $X_i$, it is immediate that the total cumulant transform is the sum of the transforms for each component. In this case, the density of $Z$ and its tail probability (equivalently its distribution) can be recovered from $\kappa(s)$ by Fourier inversion [6]

$$f_Z(z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{\kappa(s) - izs} ds$$

$$\Pr(Z > z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{\kappa(s) - izs} ds \quad (18)$$

In the following, we study the tail probability only and assume, without loss of generality, that $z \geq E[Z]$.

An application of Cauchy’s integral theorem allows us to move the integration path to the right, from the imaginary axis to a line $L = (\tilde{s} - j\infty, \tilde{s} + j\infty)$ that crosses the real axis at another point $\tilde{s}$ [13]. It is most convenient to choose $\tilde{s}$ so that $\kappa'(\tilde{s}) = z$; this point is called a saddlepoint, as complex-variable analytic functions do not reach extreme points in their domain of analyticity [13]. This point exists and is unique due to the convexity of $\kappa(s)$ [6].

Along the integration path $s = \tilde{s} + j\sigma, -\infty < \sigma < \infty$ and $(s - \tilde{s}) = j\sigma$. Using this new variable of integration, we now expand the argument of the exponential term in a Taylor series around $\tilde{s}$

$$\kappa(s) - sz = \kappa(\tilde{s}) - \tilde{s}z + \frac{\kappa''(\tilde{s})}{2!}(j\sigma)^2 + R_2(\sigma)$$

which we have used that the first derivative is zero and $R_2(\sigma)$ is a shorthand for the remaining terms in the expansion around $\tilde{s}$

$$R_2(\sigma) = \sum_{\ell=3}^{\infty} \frac{\kappa^{(\ell)}(\tilde{s})}{\ell!}(j\sigma)^\ell.$$ (20)

where we have grouped the terms with common factor $(j\sigma)^\ell$, and called the corresponding coefficient $\eta_{\ell}$, similarly for $\eta_m$, which incorporates the power of $j$ into the coefficient. The symmetry of the integrand (see (22)) implies that the integral of the terms with odd $m$ is zero; we need thus consider only the even values of $m$. The first few terms are

$$\eta_0 = \tilde{s}, \quad \eta_2 = 0$$

$$\eta_4 = -\frac{\kappa''(\tilde{s})}{3!} + \tilde{s}\frac{\kappa^{(4)}(\tilde{s})}{4!}$$

$$\eta_6 = \frac{\kappa^{(6)}(\tilde{s})}{5!} - \tilde{s}\frac{\kappa^{(6)}(\tilde{s})}{6!} - \frac{1}{2!}\left(\frac{\kappa''(\tilde{s})}{3!}\right)^2.$$ (21)

At this point, we normalize the cumulants. As the cumulants are all linear terms in $m$, the number of random variables contributing to $Z$, we get rid of this dependence on $m$ by dividing all cumulants by $\kappa''(\tilde{s})$ and denote the normalized cumulant by $\kappa''(\tilde{s})$. The coefficients $\eta_m$ become now a polynomial of $\kappa''(\tilde{s})$

$$\eta_4 = -\frac{\kappa''(\tilde{s})}{3!}\kappa''(\tilde{s}) + \tilde{s}\frac{\kappa^{(4)}(\tilde{s})}{4!}$$

$$\eta_6 = \frac{\kappa^{(6)}(\tilde{s})}{5!}\kappa''(\tilde{s}) - \tilde{s}\frac{\kappa^{(6)}(\tilde{s})}{6!}\kappa''(\tilde{s}) - \frac{1}{2!}\left(\frac{\kappa''(\tilde{s})}{3!}\right)^2.$$ (22)

The degree of the polynomials will prove useful when tracking the various terms in the final expansion.

The next problem is the evaluation of integrals of the form

$$I(m) = \frac{\eta_m}{2\pi} \int_{-\infty}^{\infty} \exp\left(-\frac{\kappa''(\tilde{s})}{2\sigma^2}\right) \frac{\sigma^m}{\sigma^2 + \sigma^2} d\sigma$$

where $m$ is an even number. The value of this integral is given in (34), in Appendix II. Setting $\nu = \frac{1}{2}\kappa''(\tilde{s})$ and $\alpha = \tilde{s}$ we obtain

$$I(m) = \eta_m \frac{1}{\sqrt{2\pi\kappa''(\tilde{s})}} \left(1 + O((\kappa''(\tilde{s}))^{-1})\right).$$ (23)

In particular, for $m = 0$ and discarding the $O(1)$ term, we recover the classical saddlepoint approximation

$$\Pr(Z > z) \approx \frac{1}{\sqrt{2\pi\kappa''(\tilde{s})}} e^{\eta_0 - iz}.$$ (24)

Note that even though this equation loses its validity for small $\tilde{s}$, we may use the original (33) and show that the probability tends to $1/2$ for $\tilde{s} \to 0$

$$\frac{1}{2\pi} \eta_0 \frac{\pi}{\tilde{s}} \text{erfc}\left(\tilde{s} \sqrt{\frac{\kappa''(\tilde{s})}{2}}\right) \exp\left(\frac{1}{2\sigma^2} \kappa''(\tilde{s})^2\right)$$

$$= \frac{1}{2} \text{erfc}\left(\tilde{s} \sqrt{\frac{\kappa''(\tilde{s})}{2}}\right) \exp\left(\frac{1}{2\sigma^2} \kappa''(\tilde{s})^2\right).$$ (25)

This yields an approximation which is uniformly valid for all values of the saddlepoint [6].

If required, higher order terms may be obtained by extending the outlined procedure. The following term is given by $m = 4$, which gives an extra term with leading coefficient $(\kappa''(\tilde{s}))^{-\frac{5}{2}}$. As $\eta_4$ is a degree-1 polynomial of $\kappa''(\tilde{s})$, the term grows rather like $(\kappa''(\tilde{s}))^{-\frac{3}{2}}$. A careful analysis of the remaining terms shows that there is only one additional term with the same factor, namely, the one corresponding to the squared
third cumulant in η_6. Putting all this information back together, the second-order saddlepoint approximation is given by

\[
\Pr(Z > z) \approx \frac{1}{2\pi} e^{-z^2} \int_{-\infty}^{\infty} e^{x^2 - x^2} \left( 1 + \frac{1}{\kappa''(\hat{s})} \left( \frac{1}{\kappa''(\hat{s})} - \frac{\kappa^3(\hat{s})}{2\kappa''(\hat{s})} \right)^2 \right)^n + O((\kappa''(\hat{s}))^{-2}) \right].
\]

This additional term in the expansion also serves as an estimate of the error made by the approximation. In general, the first term of the expansion gives a very good approximation to the real tail probability, with no need of considering extra terms.

**APPENDIX II**

**SOME INTEGRALS AND EXPANSIONS OF INTEREST**

The error complementary function is defined as

\[
\text{erfc}(x) = \frac{2}{\pi} \int_{x}^{\infty} e^{-t^2} dt.
\]

Its asymptotic series is derived by integration by parts [13] and gives

\[
\text{erfc}(x) = \frac{e^{-x^2}}{\sqrt{\pi}} \sum_{m=0}^{\infty} \left( -1 \right)^m \frac{1 \cdot 3 \cdot \cdots \cdot (2m-1)}{2^m m!} x^{2m}.
\]

Here the absolute error committed by truncating may be shown to be smaller than the first neglected term. For large values of the parameter, the approximation \( \text{erfc}(x) \approx \frac{e^{-x^2}}{\sqrt{\pi}} \) is valid. More precisely, for values of \( x \) larger than 1, the relative error in approximating \( \text{erfc}(x) \) by \( \frac{e^{-x^2}}{\sqrt{\pi}} \) is smaller than 25% (obtained by evaluation of the formula, not with an estimate of the error).

An integral that appears often in our calculations is the following [13]:

\[
\int_{-\infty}^{\infty} \exp(-\beta x^2) \frac{1}{\alpha^2 + x^2} dx = \frac{\pi}{\alpha} \text{erfc}(\alpha \beta) \exp(\alpha^2 \beta^2).
\]

Note that we may easily apply the asymptotic expansion for \( \text{erfc}(x) \).

We will also evaluate integrals of the more general form

\[
\int_{-\infty}^{\infty} \exp(-\beta x^2) \left( \frac{x^{2n}}{\alpha^2 + x^2} \right) dx
\]

where \( n \) is an integer. Their value is calculated as follows. First expand the fraction in the integrand

\[
\frac{x^{2n}}{\alpha^2 + x^2} = \sum_{m=0}^{\infty} \left( -1 \right)^{n-m} \frac{\alpha^{2n}}{\alpha^2 + x^2} x^{2(n-m)} + \sum_{m=0}^{\infty} \left( -1 \right)^{n-m} \frac{\alpha^{2n}}{\alpha^2 + x^2} x^{2n-m}.
\]

and then integrate term by term. Each term is seen to be the \( 2\nu \)th moment of a normal random variable with zero mean and variance \( (2\beta^2)^{-1} \), whose value is \( 1 \cdot 3 \cdot \cdots \cdot (2\nu - 1)/(2\beta^2)^{-\nu} \) [4]. Combining these values back into (31) and after some algebraic manipulations we get

\[
\sum_{m=0}^{\infty} \left( -1 \right)^{n-m} \frac{\alpha^{2n}}{\alpha^2 + x^2} x^{2n-m}.
\]

**APPENDIX III**

**CUMULANT TRANSFORM ASYMPTOTIC ANALYSIS**

In this appendix, we show that in the limit for large SNR, BICM behaves as a binary modulation with squared Euclidean distance

\[
d^2_{\min} \triangleq \min_{x, x' \in \mathbb{X}} d^2(x, x') = \min_{x, x' \in \mathbb{X}} |x - x'|^2.
\]

In particular, we have that

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(\hat{s})}{\text{SNR}} = -\frac{d^2_{\min}}{4}
\]

and

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa''(\hat{s})}{\text{SNR}} = 2d^2_{\min}
\]

for the AWGN channel, and

\[
\lim_{\text{SNR} \to \infty} \log \text{SNR} = -1
\]

and

\[
\lim_{\text{SNR} \to \infty} \kappa''(\hat{s}) = \delta
\]

for the fully interleaved Rayleigh-fading channel. In this appendix, and without loss of generality, assume that \( s \) is real.
A. AWGN Channel

Consider first the AWGN channel without fading. Then

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ \frac{e^{-|y|\beta}}{e^{-|z|^2}} \right] \right).
\]

We can upper-bound the term inside the expectation by upper-bounding the sum at the numerator by \(\frac{1}{|z|^2}\) and lower-bounding the sum at the denominator by \(e^{-|z|^2}\). Then

\[
\left( \frac{\sum_{z \in \mathcal{A}^{(m)}} e^{-|y|^2}}{\sum_{z \in \mathcal{A}^{(m)}} e^{-|z|^2}} \right)^{\frac{1}{2}} \leq \left( \frac{1}{2} \right)^{\frac{1}{2}} e^{-|z|^2} \tag{39}
\]

and since

\[
E \left[ e^{|z|^2} \right] < \infty;
\]

if \(s < 1\), we can use the dominated convergence theorem [4]. Note that since \(\delta = \frac{1}{2}\) for BIOS channels, this restriction poses no practical limitation to the validity of the result. We can then take the dominant terms in the sums and write that

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ \frac{e^{-|y|^2}}{e^{-|z|^2}} \right] \right)
\]

where \(x'\) denotes the signal constellation symbol closest to \(x\) in the complementary set \(\lambda^c\).

Then we have that

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( e^{-|y|^2} \right)
\]

where \(\lambda^c\) may depend on the actual mapping rule. Note, however, that the result does not. By letting \(s = \delta = \frac{1}{2}\), we then obtain that

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = -\frac{d_{\text{min}}^2}{4}.
\]

Furthermore, at large SNR, the second-order cumulant behaves as

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa''(s)}{\text{SNR}} = 2d_{\text{min}}^2
\]

which again mimics the behavior of a binary modulation with squared minimum distance \(d_{\text{min}}^2\).

B. Fully Interleaved Rayleigh-Fading Channel

In the case of the fully interleaved fading channel, we have

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ \frac{e^{-|y|^2}}{e^{-|z|^2}} \right] \right).
\]

The upper bound in (39) applies here as well and, then, for \(s < 1\), the dominated convergence theorem leads to

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right).
\]

\[
= \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= -\frac{d_{\text{min}}^2}{s^2}.
\]

where \(\gamma \geq \mathbb{E}[h]^2\) is the fading power and \(x'\) denotes again the closest point to \(x\) in the set \(\lambda^c\). Averaging over the fading we get that

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= -\frac{d_{\text{min}}^2}{s^2}.
\]

Therefore, since at large SNR

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

we obtain that the second-order cumulant behaves as

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa''(s)}{\text{SNR}} = \lim_{\text{SNR} \to \infty} \frac{1}{\text{SNR}} \times \log \left( E_{z,x,m} \left[ e^{-|y|^2} \right] \right)
\]

\[
= -\frac{d_{\text{min}}^2}{s^2}.
\]

By letting \(s = \delta = \frac{1}{2}\), it is easy to verify that at the saddlepoint

\[
\lim_{\text{SNR} \to \infty} \frac{\kappa''(\delta)}{\text{SNR}} = 8
\]

as in the binary case.

REFERENCES

where $x_\ell \in \mathbb{C}^m$ is the (normalized) transmitted signal vector and $y_\ell \in \mathbb{C}^m$ is the received signal vector. Here $p$ is the number of transmit antennas and $n$ is the number of receive antennas. $H_\ell \in \mathbb{C}^{m \times p}$ consists of independent and identically distributed (i.i.d.) standard complex normal entries. $R_\ell \in \mathbb{C}^{p \times p}$ is the channel matrix. $P = \text{diag}[c_1, \ldots, c_p] \in \mathbb{R}^{p \times p}$; $c_\ell = c_{\ell \ell}^{-1}$, where $c_\ell$ is the signal-to-noise ratio (SNR) for the $\ell$th spatial stream. This definition of SNR is consistent with [1, Sec. 7.4]. $H = H_\ell R_\ell^{1/2} P^{1/2} \in \mathbb{C}^{m \times p}$ is treated as the channel matrix. $n_\ell \in \mathbb{C}^m$ is the complex noise vector and is assumed to have zero mean and identity covariance. Note that the power matrix $P$ has terms involving the variance of the noise. The correlation matrix $R_\ell$ and power matrix $P$ are assumed to be nonrandom. Also, we restrict our attention to $p \leq m$.

We consider the popular linear minimum mean-square error (MMSE) receiver. Conditional on the channel matrix $H$, the signal-to-interference-plus-noise ratio (SINR) on the $k$th spatial stream can be expressed as (e.g., [1–6])

$$
\text{SINR}_k = \frac{1}{\text{MMSE}_k} = 1 - \frac{1}{\left[(I_p + \frac{1}{n_\ell} H^H \sigma_k) \right]_{kk}}
$$

where $I_p$ is a $p \times p$ identity matrix, and $H^H$ is the Hermitian transpose of $H$. Note that (2), in the same form as equation (7.49) of [1], is derived based on the second-order statistics of the input signals, not restricted to binary signals.

For binary inputs, Verdú [4, eq. (6.47)] provides the exact formula for computing the bit-error rate (BER) (also see [7]). Conditional on $H$, this BER formula requires computing $2^{n_\ell}$ Q-functions. To compute BER unconditionally, we need to sample $H$ enough times (e.g., $10^7$) to get a reliable estimate. When $p \geq 32$ (or $p \geq 64$), the computations become intractable [4, 8].

Recently, study of the asymptotic properties of multiuser receivers (e.g., [2–4], [6], [8]–[11]) has received a lot of attention. Works that relate directly to the content of this correspondence include Tse and Hanly [11] and Verdú and Shamai [6], who independently derived the asymptotic first moment of SINR for uncorrelated channels. Tse and Zeitouni [3] proved the asymptotic Normality of SINR for the equal power case, and commented on the possibility of extending the result to the unequal powers scenario. Zhang et al. [12] proved the asymptotic Normality of the multiple-access-interference (MAI), which is closely related to SINR. Guo et al. [8] proved the asymptotic Normality of the decision statistics for a variety of linear multiuser receivers. [8] considered a general power distribution and corresponding unconditional asymptotic behavior.

Based on the asymptotic Normality results, Poor and Verdú [2] (also in [4, 8]) proposed using the limiting BER (denoted by $\overline{\text{BER}}_{\infty}$) for binary modulations, which is a single Q-function

$$
\overline{\text{BER}}_{\infty} = Q\left(\sqrt{\text{E}(\text{SINR}_k)}\right) = \int_0^{\infty} e^{-t^2/2} dt
$$

where $\text{E}(\text{SINR}_k)$ denotes the asymptotic first moment of SINR$_k$.

Equation (3) is convenient and accurate for large dimensions. However, its accuracy for small dimensions is of some concern. For instance, [8] compared the asymptotic BER with simulation results, which showed that even with $p = 64$ there existed significant discrepancies. In general, (3) will underestimate the true BER. For example, in our simulations, when $m = 16, p = 8$, SNR = 15 dB, the asymptotic BER given by (3) is roughly $10^{-6}$ of the exact BER. In current practice, code-division multiple-access (CDMA) channels with $m, p$ between 32 and 64 are typical and in multiple-antenna systems arrays of 4 antennas are typical but arrays with 8 to 16 antennas would be feasible in the near future [9]. Therefore, it would be useful if
