THE EFFECT OF Sn ON Pt/C CATALYSTS FOR THE METHANOL ELECTRO-OXIDATION

T. FRELINK, W. VISSCHER and J. A. R. VAN VEEN
Laboratory for Inorganic Chemistry and Catalysis, Eindhoven University of Technology, P.O. Box 513, Eindhoven, The Netherlands

(Received 4 October 1993; accepted 17 January 1994)

Abstract—The effect of Sn for the methanol oxidation in sulfuric acid is investigated using electro-deposited Pt and carbon supported Pt. The preparation has a considerable influence, as the Sn effects range from a small increase to a decrease in methanol oxidation activity. Sn is believed to act through the activation of H₂O. The optimum Sn surface coverage is found to be low; of the order of 10%.

Key words: electrocatalysis, methanol, Pt, Pt/C, promotion by Sn.

INTRODUCTION

The direct methanol fuel cell has been designated as a candidate for electric power sources. Since an acid electrolyte is preferred, the choice of the anode is confined to Pt. The performance of Pt for the methanol oxidation is still rather poor, but it is possible to enhance its activity by introducing a second metal, like Ru or Sn. Ru has been shown to be a good promoter[1, 2]. For Sn the effect is not yet clear. In early papers[3, 4] large enhancement factors (50-100) were claimed for smooth and electrodeposited Pt on which Sn was deposited. Later, other authors found considerably smaller and sometimes even negative effects[5-8]. The positive effect of Sn is mainly attributed to activation of adsorbed H₂O, that is, Sn is responsible for the deliverance of an oxygen atom to the methanol adsorbate to oxidize it to CO₂. Another explanation is the ligand effect, ie Sn influences the Pt-oxide formation or the Pt adsorbate binding. The effect of Sn for carbon supported Pt catalysts is substantially lower (ca. 10). Moreover the influence of Pt particle size on the effect of Sn is not yet clear. A complicating fact in the comparison of the literature data is the large variety in preparation methods, which might be the cause of the different results.

The aims of the present paper are to: (i) explore whether variations in the way in which Sn is incorporated in the Pt catalyst do indeed lead to variations in its effect on the methanol oxidation activity of Pt based electrodes; and (ii) find out whether any positive effects are in fact consistent with the view of H₂O activation, taking into account that we and others have found that a carbon-based Pt catalyst with -4 nm particles already appear to have optimum H₂O activation ability[9, 10].

EXPERIMENTAL

Catalyst preparation

Electrodeposited Pt was prepared on a smooth Pt electrode of 6 cm², from a 2 g H₂PtCl₆/100 ml solution with a current of 5 mA cm⁻² for 15 min. The real Pt surface area was 101 cm² after electrodeposition, as measured from the hydrogen desorption area. Sn was added by immersing the electrode, which was electrochemically pre-covered with hydrogen, in 0.3 g l⁻¹ SnO in 36% KOH at 80°C.

All carbon supported catalysts were prepared with Vulcan XC-72R (325 m² g⁻¹) (Cabot) as support. Three different catalysts were used.

(A) Colloidal Pt/C was prepared by reducing H₂PtCl₆ (Drijfhout) with sodium-citrate solution under reflux[11]. The obtained Pt sol was then added to the suspended carbon support. After filtration, the filtrate was found to be colourless, indicating that all Pt was adsorbed on the support. The catalyst was thereafter washed and dried at 125°C. TEM measurements showed that the mean Pt particle size is ca. 4 nm. Sn was added to this catalyst by immersion of the electrode (which was previously kept at a potential of E = -0.65 V vs. mse for 60 s) in a solution of either 0.3 g l⁻¹ SnO (Aldrich) in 36% KOH (Merck) at 80°C, or an aqueous solution of 10 g l⁻¹ SnCl₂ at 23°C. The amount of Sn on the electrode was varied by varying the adsorption time.

(B) PtSn sol was prepared by adding SnCl₂ (Aldrich) to a boiling solution of H₂PtCl₆ and sodium-citrate in water, in a stoichiometry of Pt:Sn 10:1. The obtained Pt sol was then added to the suspended carbon support. After filtration, the filtrate was found to be colourless, indicating that all Pt was adsorbed on the support. The catalyst was thereafter washed and dried at 125°C. TEM measurements showed that the mean Pt particle size is ca. 4 nm. Sn was added to this catalyst by immersion of the electrode (which was previously kept at a potential of E = -0.65 V vs. mse for 60 s) in a solution of either 0.3 g l⁻¹ SnO (Aldrich) in 36% KOH (Merck) at 80°C, or an aqueous solution of 10 g l⁻¹ SnCl₂ at 23°C. The amount of Sn on the electrode was varied by varying the adsorption time.

(C) Impregnated PtSn/C was prepared by mixing the carbon support with a dissolved 5:1 Pt–Sn chloride complex, this compound is used in the colorimetric detection of Pt[12]. The mixture was boiled for 2 h; formaldehyde (Merck) was then added as a reductor. After one more hour of reflux the catalyst was filtered, washed with water and dried at 125°C.

Electrode preparation

The electrodes of the carbon supported Pt catalysts were prepared by pressing a mixture of the catalyst and a Teflon suspension on a Pt current collector. The electrode was dried at 125°C and sintered.
Fig. 1. Methanol oxidation activity of electrodeposited Pt before and after Sn immersion for the methanol oxidation: (---) Pt-Sn; (- - -) Pt. 0.5 M H₂SO₄, 0.1 M CH₃OH.

at 340°C for 2 h. The final Teflon content of all electrodes was ca. 20%.

Electrochemical characterization

The catalyst surfaces were characterized by cyclic voltammetry at room temperature using a computer controlled Autolab potentiostat (Eco chemie). Potentiodynamic cycling was generally carried out between -0.65 and +0.6 V vs. MSE (E = 0.65 V vs. rhe) in 0.5 M H₂SO₄. A Pt sheet was used as a counter electrode. Pt surface areas and Sn surface coverages were determined from the hydrogen desorption area of the anodic cyclic voltammetric sweep assuming that 1 cm² of Pt required 210 μC.[13]

The methanol oxidation was measured in 0.1 M CH₃OH (Merck)/0.5 M H₂SO₄ with a potential sweep with a sweep rate of 5 mVs⁻¹; it was established that no significant different results were obtained with lower sweep rates. The change in activity will be compared for each catalyst with the Sn-free electrode.

Differential electrochemical mass spectrometry measurements were carried out in the same electrolytes with an experimental setup similar to that of Vielstich et al.[14].

RESULTS

Electrodeposited Pt

Immersion (during 15 min) of electrodeposited Pt resulted in a Sn coverage of 20%. The effect of this Sn coverage on the oxidation of methanol is shown in Fig. 1. In the low potential region the methanol oxidation activity is a factor 10 larger in the presence of Sn. This is in good agreement with the results of Iwasita et al.[15] who found an enhancement with a factor of 7.5. It is however substantially smaller than the 100-fold increase at -0.15 V found by Janssen and Moolhuysen[3]. It is further relevant to note that, also in contrast to their results, Sn does not influence the position of the Pt-O reduction peak. By varying the immersion time of the electrodeposited Pt, Sn coverages ranging up to 100% were obtained. Measurements of the activity as a function of Sn surface coverage show that high Sn coverages (>50%) give a decrease in activity in the low potential region, whereas Sn coverages below 50% give an increase in activity. The optimum Sn coverage is below 20%.

Catalyst A

Figure 2A shows the cyclic voltammogram of the Pt/C catalyst (A) as prepared and after Sn immersion. The hump at ca. 0 V indicates oxidates of Sn and no change in the Pt-oxide reduction is observed.
(Fig. 2B). By comparing the anodic hydrogen area it is seen that Sn preferentially covers the sites that strongly bind hydrogen. The Sn coverages for two different samples were calculated to be \( \theta_{Sn} = 0.26 \) and \( \theta_{Sn} = 0.13 \). The effect of these Sn coverages on the oxidation of methanol is shown in Fig. 3. In the potential region between -0.2 and 0 V the activity is increased, the catalyst with 13% Sn has the highest activity. At higher potentials however the activity is lower than that of pure Pt/C. This confirms that already at low coverage Sn can also act as a surface blocking agent vs-\( \omega \)-\( \nu \) methanol adsorption[3].

Immersion in SnCl\(_4\) solutions always resulted in a Sn coverage higher than 50%. At this high Sn coverage still some enhancement in methanol oxidation activity was found in the low potential region. DEMS measurements showed that the CO\(_2\) production during the methanol oxidation is indeed somewhat higher and starts at a lower potential (Fig. 4). Similar results were obtained for CO oxidation.

Fig. 4. Effect of high Sn coverage on the methanol oxidation: (A) Current potential curve; (B) mass potential curve. (---) \( \theta_{Sn} = 0 \); (---) \( \theta_{Sn} = 0.5 \). 0.5 M H\(_2\)SO\(_4\), 0.1 M CH\(_3\)OH, \( v = 5 \) mV s\(^{-1}\).
Oxidation of a pre-adsorbed species (either from CO or CH$_3$OH) gives a cathodic shift of approximately 0.1 V in CO$_2$ production potential, as is shown in Fig. 5, again indicating that Sn promotes the oxidation of the adsorbed residue but also hampers the methanol adsorption.

**Catalyst B**

XPS measurement of the colloidal PtSn/C catalyst B shows the presence of mainly Pt metal, with a small amount of oxidized species; the Sn spectra show that only oxidized Sn is present. The Pt:Sn ratio was found to be 8:1. The cyclic voltammogram of this catalyst with and without Sn is given in Fig. 6A. No change in the Pt–oxide reduction potential occurs. The Sn oxidation is observed at ca. 0 V. Upon cycling of the electrode the Sn peak diminishes, indicating that Sn disappears from the surface. This is also indicated by an increase of the anodic hydrogen area. No preference for strongly bonded hydrogen is seen for this catalyst. As soon as the Sn oxidation peak was no longer observed and the hydrogen area did not increase any further, we assumed that the surface was free of Sn, so that the electrode surface could be established. Estimation of the Sn surface coverage is difficult since we have found[9] that Pt particles on a carbon support grow during extensive cycling. However, if it is assumed that there is no particle growth, we estimated an Sn coverage of at least $\theta_{\text{Sn}} = 0.07$, which is close to the Pt:Sn ratio determined with XPS. This suggests that there is no strong Sn enrichment of the PtSn particle surface.

The methanol oxidation activity on PtSn/C as given in Fig. 6B is about a factor 2 higher than on the catalyst free of Sn.

**Catalyst C**

XPS measurements of the impregnated catalyst show Pt metal with a relatively large amount of oxidized species; the Sn spectra show the presence of an oxidized Sn species. The ratio of Pt:Sn is found to be 4:3, which implies a very strong Sn enrichment of the surface. No oxidation peak for Sn could be
Effect of Sn on Pt/C catalysts

Fig. 7. Methanol oxidation on impregnated PtSn catalyst C: (——) PtSn/C; (----) Pt/C. 0.5 M H$_2$SO$_4$, 0.1 M CH$_3$OH, $v = 10$ mV s$^{-1}$.

detected by the cyclic voltammogram of this catalyst. Upon cycling however the hydrogen area increased like for catalyst B and the methanol oxidation activity reached a value representative of an impregnated catalyst without Sn[9]. The methanol oxidation was found to be lower than for the Sn free catalyst (Fig. 7).

**GENERAL DISCUSSION**

No change in the Pt-oxide reduction potential is observed in the presence of Sn for any of the Pt catalysts. Sn does not seem to influence the Pt-oxide formation and a ligand effect of Sn therefore is not very likely.

For the purpose of this discussion the methanol oxidation can be written as:

\[
\begin{align*}
\text{CH}_3\text{OH} & \rightarrow \text{COH} + 3\text{H}^+ + 3e^-, \\
\text{H}_2\text{O} & \rightarrow \text{OH}^- + \text{H}^+ + e^-, \\
\text{COH} + \text{OH}^- & \rightarrow \text{CO}_2 + 2\text{H}^+ + 2e^-.
\end{align*}
\]

We take Sn to promote the activation of water, equation (2), which proceeds difficultly on Pt itself. A secondary effect of Sn is to impede the methanol adsorption, hence the optimal Sn coverage must be low. Evidence exists that Sn covers two Pt sites[16], whereas methanol needs an ensemble of 5-6 Pt sites. The amount of these ensembles rapidly decreases with an increasing Sn coverage. This explains why at high Sn surface coverages, where a cathodic shift of 0.1 V for the oxidation of an adsorbate is observed, the steady-state activity is still low (low rate of formation of the adsorbate). The enhancement in methanol oxidation activity is highest for the electrodeposited Pt, where the H$_2$O activation is most difficult. The activity of the Sn promoted Pt is higher than that of Sn-free colloidal Pt with optimum particle size, if compared per real surface area.

The enhancement in the case of colloidal Pt, with Pt particles of ca. 4 nm, is still about a factor 2, indicating that Sn transfers its oxygen to the adsorbed residue at a higher rate than Pt. We observed that Pt particles of ~4 nm have an optimal water activation ability[9].

Impregnated Pt particles are known to be substantially smaller (~2 nm) and thus “over-active” in water activation[9]. No enhancement, on the contrary, is found for the smallest Pt particles. This over-activity diminishes the amount of free adsorption sites for methanol, addition of Sn will only decrease this amount further and thus lower the methanol oxidation activity. This could explain the decrease in activity for the impregnated PtSn catalyst, but incomplete reduction of the catalyst might also be of influence, as XPS spectra show higher oxidation states for Pt and Sn in the impregnated catalyst. The fact that XPS measurements show a high amount of Sn (~40%) should not be of any influence, as with immersed electrodes Sn coverages as high as 50% still show a small enhancement in activity.

**CONCLUSION**

It appears that different preparation methods may indeed account for the different results on the effect of Sn. A Pt particle size effect may play a role as well. There is no indication that Sn acts via a ligand effect, a water activation effect seems to be most likely.
