The just-in-time concept decrees not to accept ordered goods before their due dates in order to
avoid inventory cost. This bounces the inventory cost back to the manufacturer: products that are
completed before their due dates have to be stored. Reducing this type of storage cost by preclusion
of early completion conflicts with the traditional policy of keeping work-in-process inventories
down. This paper addresses a single-machine scheduling problem with the objective of minimizing
total inventory cost, comprising cost associated with work-in-process inventories and storage cost
as a result of early completion. The cost components are measured by the sum of the job comple-
tion times and the sum of the job earlinesses. This problem differs from more traditional scheduling
problems, since the insertion of machine idle time may reduce total cost. The search for an optimal
schedule, however, can be limited to the set of job sequences, since for any sequence there is a
clear-cut way to insert machine idle time in order to minimize total inventory cost. We apply
branch-and-bound to identify an optimal schedule. We present five approaches for lower bound
calculation, based upon relaxation of the objective function, of the state space, and upon Lagran-
gian relaxation.

1980 Mathematics Subject Classification (1985): 90B35.
Key Words and Phrases: just-in-time manufacturing, inventory cost, work-in-process inventory,
earliness, tardiness, machine idle time, branch-and-bound algorithm, Lagrangian relaxation.
1. Introduction

The just-in-time concept has affected the attitude towards inventories significantly. In order to keep inventories down, there is a reluctance to accept ordered goods prior to their due dates. This implies that manufacturers have to store early completed goods before they can be shipped to their destinations. This has added a relatively new aspect to machine scheduling theory: the preclusion of earliness.

In principle, earliness can be avoided by allowing machine idle time, thereby deferring jobs. Machine idleness, however, runs counter to the natural instinct to minimize work-in-process inventories, to maximize machine utilization, and to observe due dates.

Within this context, we address the following situation. A set \( J = \{J_1, \ldots, J_n\} \) of \( n \) independent jobs has to be scheduled on a single machine, which is continuously available from time zero onwards. The machine can handle at most one job at a time. Job \( J_j (j = 1, \ldots, n) \) requires a positive integral uninterrupted processing time \( p_j \) and should ideally be completed exactly on its due date \( d_j \). A schedule specifies for each job \( J_j \) a completion time \( C_j \) such that the jobs do not overlap in their execution. The order in which the machine processes the jobs is called the job sequence. For a given schedule, the earliness of \( J_j \) is defined as \( E_j = \max\{0, d_j - C_j\} \) and its tardiness as \( T_j = \max\{0, C_j - d_j\} \). In addition, we define maximum earliness as \( E_{\text{max}} = \max_{1 \leq j \leq n} E_j \) and maximum tardiness as \( T_{\text{max}} = \max_{1 \leq j \leq n} T_j \). Accordingly, \( J_j \) is called early, just-in-time, or tardy if \( C_j < d_j \), \( C_j = d_j \), or \( C_j > d_j \), respectively.

In this paper, we follow the terminology of Graham, Lawler, Lenstra, and Rinnooy Kan (1979) to classify scheduling problems. Deterministic scheduling problems are classified according to a three-field notation \( \alpha|\beta|\gamma \), where \( \alpha \) specifies the machine environment, \( \beta \) the job characteristics, and \( \gamma \) the objective function. For instance, \( \alpha = 1 \) refers to a single machine, \( \beta = \text{pmtn} \) signifies that the jobs may be preempted, that is, the processing of a job may be interrupted and resumed later, and \( \gamma = \Sigma C_j \) means that the objective is to minimize the sum of the job completion times. Since earliness is nonincreasing in the job completion times, it may generally be advantageous to permit machine idle time. The inclusion of the acronym \( \text{nnmit} \) in the second field signifies that no machine idle time is allowed.

Three types of single-machine scheduling problems involving job earliness have been considered in the literature. The best-known is the minimization of \( E_{\text{max}} \). If machine idle time is not allowed, then the problem is solved by scheduling the jobs in nondecreasing order of \( d_j - p_j \); this is known as the minimum slack time order. If machine idle time is permitted, then the problem is trivial: for any given sequence, we defer the jobs until all are just-in-time or tardy. This approach also applies to 1\( | \Sigma E_j \); but, surprisingly, 1\( | \text{nnmit} | \Sigma E_j \) is \( \text{NP-hard} \) in the ordinary sense (Du and Leung, 1990). The third problem is to maximize \( \Sigma w_j E_j \), where \( w_j \) is the weight of job \( J_j \), denoted as 1\( | - \Sigma w_j E_j \); this problem is solvable in pseudopolynomial time by an algorithm due to Lawler and Moore (1969).

The combination of earliness with another performance measure, reflecting other considerations, takes us into the arena of bicriteria scheduling. The state of the art, as far as a measure of earliness is concerned, is as follows. For the 1\( | \text{pmtn}, \text{nnmit} | \alpha \Sigma C_j + \beta E_{\text{max}} \) problem, Hoogeveen and Van de Velde (1990) present an algorithm that runs in \( O(n^4) \) time. They show that the same algorithm also solves 1\( | \alpha \Sigma C_j + \beta E_{\text{max}} \) in case \( \alpha \geq \beta \). Hoogeveen (1990) presents algorithms that solve 1\( | \alpha E_{\text{max}} + \beta T_{\text{max}} \) and 1\( | \text{nnmit} | F(E_{\text{max}}, T_{\text{max}}) \) in \( O(n^2 \log n) \) and \( O(n^2) \) time; \( F \) is here an arbitrary nondecreasing function of \( E_{\text{max}} \) and \( T_{\text{max}} \). For the 1\( | \text{nnmit} | \Sigma (\alpha E_j + \beta T_j) \) problem, Ow and Morton (1989) propose a local search method to generate approximate solutions. A voluminous part of research is concerned with common due date scheduling. Here, we have \( d_j = d (j = 1, \ldots, n) \); the
objective is to minimize some function of earliness and tardiness. A survey of problems, algorithms, and computational complexity is provided by Baker and Scudder (1990).

In this paper, we consider the problem of minimizing total inventory cost, which is supposed to comprise two components: cost due to work-in-process inventory and storage cost as a result of early completions. These components are assumed to depend linearly on the sum of job completion times and the sum of job earliness. If we let $\alpha$ and $\beta$ denote the cost per unit time for work-in-process inventory and storage of finished product, respectively, then the total inventory cost for a given schedule $\sigma$ is

$$f(\sigma) = \alpha \sum_{j=1}^{n} C_j + \beta \sum_{j=1}^{n} E_j.$$  

Without loss of generality, we assume $\alpha$ and $\beta$ to be integral, positive, and relatively prime. Since we have by definition that $E_j = T_j - C_j + d_j$ for $j = 1, \ldots, n$, the objective function can alternatively be written as

$$(\alpha - \beta) \sum_{j=1}^{n} C_j + \beta \sum_{j=1}^{n} (T_j + d_j).$$

If $\alpha \geq \beta$, then this a regular objective function, and hence there is an optimal schedule without machine idle time. The case $\alpha = \beta$ reduces to $1 \mid \sum T_j$, which is $\mathcal{NP}$-hard in the ordinary sense (Du and Leung, 1990). Garey, Tarjan, and Wilfong (1988) prove that the case $\alpha < \beta$ is $\mathcal{NP}$-hard, too. We note that the case $\beta > n\alpha$ reduces to $1 \mid r_j \sum C_j$, which is also $\mathcal{NP}$-hard in the strong sense (Lenstra, Rinnooy Kan, and Brucker, 1977).

We address the case $\beta \geq \alpha$, in which the insertion of machine idle time may be advantageous. Our purpose is to find a feasible schedule $\sigma$ that minimizes $f(\sigma)$. This problem was introduced by Fry and Keong Leong (1987a), who formulate it as an integer linear program. They used a standard code to find an optimal schedule. Not surprisingly, the proposed method solves problems up to 12 jobs only.

The search for an optimal schedule, however, can be reduced to a search over the $n!$ different job sequences, as there is a clear-cut method to insert machine idle time to minimize total cost for a given sequence. This method, which requires $O(n^2)$ time, is described in Section 2.

The freedom to leave the machine idle singles out our problem from most concurrent research on scheduling problems with earliness penalties. To our knowledge, this is the first paper that presents a branch-and-bound algorithm for a single-machine scheduling problem with a nonregular objective function, where insertion of machine idle time is allowed. Machine idle time affects the design of a branch-and-bound algorithm significantly. In Section 3, we discuss some components of the algorithm such as the upper bound, the branching rule, the search strategy, and the dominance rules. Lower bounds are presented in Section 4. The range of the due dates in proportion to the processing times mainly dictates when the first job is started and how much machine idle time is inserted between the execution of the jobs. To cope with the variety of due date patterns, we propose five approaches for lower bound computation. Each of these methods seems to be suitable for a certain class of instances. Some computational results are reported in Section 5; conclusions are presented in Section 6.
2. The insertion of idle time for a given sequence

The search for an optimal schedule can be reduced to a search over the \( n! \) different job sequences, as there is a clear-cut procedure to insert machine idle time so as to minimize total cost for a given sequence.

This procedure, however, is not new. Similar methods have been presented (cf. Baker and Scudder, 1990), including the ones proposed by Fry and Keong Leong (1987b) for the \( 1 \mid \sum (\alpha C_j + \beta E_j + \gamma T_j) \) problem and by Garey, Tarjan, and Wilfong (1988) for the \( 1 \mid \sum E_j + T_j \) problem. This is not surprising: as we have already noted, \( T_j = C_j + E_j - d_j \) for all \( j \); for specific choices for \( \alpha \) and \( \beta \), our problem is equivalent with theirs.

Suppose that the scheduling order is \( \sigma = (J_1, \ldots, J_n) \). Accordingly, \( C_j = \sum_{k<j} p_k \) is the earliest possible completion time of \( J_j \) in this sequence. We introduce a vector \( x = (x_1, \ldots, x_n) \) of variables, with \( x_j \) \((j = 1, \ldots, n)\) denoting the amount of idle time immediately before the execution of \( J_j \). The actual completion time of \( J_j \) is then \( C_j = C_j + \sum_{k<j} x_k \). The problem of minimizing inventory cost for the given job sequence is then equivalent to determining values \( x_j \) \((j = 1, \ldots, n)\) that minimize

\[
\alpha \sum_{j=1}^{n} (C_j + \sum_{k=j}^{n} x_k) + \beta \sum_{j=1}^{n} \max \left( 0, d_j - C_j - \sum_{k=j}^{n} x_k \right)
\]

subject to

\[
x_j \geq 0, \quad \text{for } j = 1, \ldots, n.
\]

By the introduction of auxiliary variables \( E_j \) denoting the earliness of \( J_j \) \((j = 1, \ldots, n)\), we can easily transform this problem into a linear programming problem. We know therefore that the optimum is attained in a vertex of the unspecified LP polytope. In addition, we know that the optimal \( x_j \) are integral, since the due dates, the processing times, \( \alpha \), and \( \beta \) are integral. A necessary condition for \( x \) to be optimal is that all existing primitive directional derivatives at \( x \) are non-negative. The primitive directional derivatives are equal to the change of the scheduling cost if \( x_j \) is increased by one unit, and the change of the scheduling cost if \( x_j \) is decreased by one unit, for \( j = 1, \ldots, n \). The increase of \( x_j \) by one unit only affects \( J_j \) and the jobs succeeding \( J_j \) up to the first period of machine idle time after \( J_j \).

We call these jobs the immediate successors of \( J_j \). Let \( Q_j \) denote the set containing \( J_j \) and its immediate successors, let \( n_j \) be the number of early jobs in \( Q_j \), and let \( g_j \) be the primitive directional derivative for increasing \( x_j \). We have then that \( g_j = \alpha \mid Q_j \mid - \beta n_j \). Recall that each \( J_j \) is ideally completed on its due date \( d_j \).

Using the above observations, we develop an inductive procedure for finding an optimal schedule for \( \sigma \). This procedure finds an optimal schedule for the subsequence \((J_l, \ldots, J_1)\), given an optimal schedule for the subsequence \((J_{l-1}, \ldots, J_1)\), for \( l = 2, \ldots, n \). The first step is to find out whether putting \( C_l = d_l \) is feasible; if so, then we have an optimal schedule for \((J_l, \ldots, J_1)\). Suppose \( C_l = d_l \) is not feasible, because \( J_l \) overlaps with some other job. We then tentatively put \( C_l = C_{l-1} - p_{l-1} \), and compute the optimal deferral of the jobs in \( Q_l \), disregarding the jobs not in \( Q_l \). The optimal deferral, denoted by \( \delta \), is dictated by the first point where \( g_l \) becomes non-negative. This deferral is feasible if \( \delta \) is no larger than the length of the period of idle time immediately after the last job in \( Q_l \); let this length be \( \delta_{\text{max}} \). If \( \delta \leq \delta_{\text{max}} \), then we get an optimal schedule for \((J_l, \ldots, J_1)\) by deferring the jobs in \( Q_l \) by \( \delta \). If \( \delta > \delta_{\text{max}} \), then we defer the jobs in \( Q_l \) by \( \delta_{\text{max}} \). At this point, we repeat the process for \( J_l \); we update \( Q_l \), and evaluate if additional deferral of the jobs in \( Q_l \) is advantageous. We now give a step-wise description of the idle time insertion algorithm.
Idle time insertion algorithm

Step 0. $C_1 \leftarrow d_1; I \leftarrow 2.$
Step 1. If $I = n+1$, go to Step 9.
Step 2. Put $C_I \leftarrow \min \{d_I, C_{I-1} - p_{I-1}\}$. If $C_I = d_I$, then go to Step 8.
Step 3. Determine $Q_I$ and evaluate $g_I$. If $g_I \geq 0$, then go to Step 8.
Step 4. Compute $E_j$ for each job $J_j \in Q_I$.
Step 5. Compute $O_{\text{max}}$, i.e., the length of the period of idle time immediately after the last job in $Q_I$.
Step 6. Let $a \leftarrow L(I \setminus Q_I) < X_{\text{al}}$ and $k \leftarrow |Q_I| - a$. Determine the $k$th smallest value of the earlinesses of the jobs in $Q_I$; this value is denoted as $E_{[k]}$. If the jobs in $Q_I$ are deferred by $\delta = E_{[k]}$, then at most $a$ jobs in $Q_I$ remain early; due to the choice of $a, g_I$ then becomes non-negative.
Step 7. Defer the jobs in $Q_I$ by $\Delta = \min \{\delta, \delta_{\text{max}}\}$. If $\delta > \delta_{\text{max}}$, then go to Step 3.
Step 8. $I \leftarrow I + 1$; go to Step 1.
Step 9. An optimal schedule for the sequence $(J_n, \ldots, J_1)$ has been determined.

Theorem 1. The idle time insertion algorithm generates an optimal schedule for a given sequence.

Proof. The proof proceeds by induction. The algorithm clearly produces the optimal schedule in case of a single job. Suppose that we want to find an optimal schedule for the sequence $(J_1, \ldots, J_1)$, having an optimal schedule for the sequence $(J_{I-1}, \ldots, J_1)$ available. There are two cases to consider. First, suppose $d_I \leq C_{I-1} - p_{I-1}$; in this case, we let $C_I = d_I$, and retain the completion times of the other jobs; this specifies an optimal schedule for the sequence $(J_1, \ldots, J_1)$. Suppose now $d_I > C_{I-1} - p_{I-1}$; for this case, deferring $J_{I-1}$ and thereby its immediate successors, i.e., the jobs contained in the set $Q_{I-1}$, may be advantageous. We can compute the cost of deferring $Q_{I-1}$ by one unit; the benefit of deferring $J_I$ by one unit is equal to $\beta - \alpha$. If the cost is higher than or equal to the benefit, then we put $C_I = C_{I-1} - p_{I-1}$, and we have an optimal schedule for the sequence $(J_1, \ldots, J_1)$; otherwise, we defer the jobs in $Q_{I-1}$ by one unit, and evaluate whether additional deferral is advantageous. The idle time insertion algorithm shortcuts this procedure by computing the break-even point, that is, the point where additional deferral is not advantageous. □

Consider the example for which the data are given in Table 1. Let $\alpha = 1$ and $\beta = 4$. We construct the optimal schedule for the sequence $(J_3, J_2, J_1)$. First, we put $C_1 = d_1 = 15$. Next, we let $C_2 = d_2 = 10$, as $d_2 \leq C_1 - p_1$. Note that $d_3 > C_2 - p_2$. Therefore, we tentatively put $C_3 = C_2 - p_2 = 7$, and consider deferring $J_3$ and $J_2$. Apparently, we have $Q_3 = (J_3, J_2), n_3 = 1, g_3 = 2\alpha - \beta < 0$, and $E_{[2]} = 3$. However, $\delta_{\text{max}} = C_3 - p_3 = 2$, therefore, we defer $J_2$ and $J_3$ by 2 units. At this point, the three jobs are processed consecutively. Now we have $g_3 = 3\alpha - \beta$, and additional deferral is still advantageous. As $E_{[3]} = 1$, we insert one more unit of machine idle time. The optimal schedule for each subproblem is depicted in Figure 1.

The algorithm runs in $O(n^2)$ time. A complete run through the main part of the algorithm, i.e., steps 2 through 8, takes $O(n)$ time: this is needed to identify the set $Q_I$, to compute the primitive directional derivative $g_I$, the values $\delta_{\text{max}}$ and $\delta$, and to defer the jobs, if necessary. The value $\delta$ is determined in $O(n)$ time through a median-finding technique; see Aho, Hopcroft, and Ullman (1982). After each run through the main part of the algorithm, a gap between two successive jobs is closed. As at most $n-2$ such gaps exist, the algorithm runs in $O(n^2)$ time. For the case $2\alpha = \beta$, i.e., for the problem

Figure 1. Schedules for the example.

1 | $||\Sigma(E_j + T_j)$, Garey, Tarjan, and Wilfong (1988) show that the idle time insertion procedure can be implemented to run in $O(n \log n)$ time.

The problem of inserting machine idle time can also be solved by a symmetric procedure starting with the first job in $\sigma$. Because of our specific branching rule, however, we choose to start at the end.

In the remainder, we use the terms sequence and schedule interchangeably. Unless stated otherwise, $\sigma$ also refers to the optimal schedule for the sequence $\sigma$ and to the set of jobs in the sequence $\sigma$. From now on, we let $p(\sigma) = \Sigma_{j \in \sigma} p_j$.

3. The branch-and-bound algorithm

We adopt a backward sequencing branching rule: a node at level $k$ of the search tree corresponds to a sequence $\pi$ with $k$ jobs fixed in the last $k$ positions. We assume from now on that the first job in a partial schedule $\pi$ is not started before time $p(\pi)$; this additional restriction, imposed to leave space for the remaining jobs, is easily incorporated in the idle time insertion algorithm. Let $f(\pi)$ denote the minimal inventory cost for $\pi$. Let $\overline{f}(\pi)$ denote the minimal inventory cost for $\pi$ if the first job may be started before time $p(\pi)$; the notation $\overline{f}(\pi)$ is only needed in this section. For any partial schedule $\pi$, we have $f(\pi) \geq \overline{f}(\pi)$.

We employ a depth-first strategy to explore the tree: at each level, we generate the descendant nodes for only one node at a time. At level $k$, there are $n-k$ descendant nodes: one for each unscheduled job. The completion times for the jobs in $\pi$ are only temporary. Branching from a node that corresponds to $\pi$, we add some job $J_j$ leading to the sequence $J_j \pi$. Subsequently, we determine the associated optimal schedule for $J_j \pi$, and possibly defer some jobs in $\pi$. We branch from the nodes in order of non-increasing due dates of the associated jobs. Before entering the search tree, we determine an upper bound on the optimal solution value. We use the optimal schedule corresponding to the minimum slack time sequence as an initial solution, and try to reduce its cost by pairwise adjacent interchanges.

A node is discarded if its associated partial schedule $\pi$ cannot lead to a complete schedule with cost less than $UB$; $UB$ denotes the currently best solution value. Let $LB(\pi)$ be some lower bound on the minimal cost of scheduling the jobs in the set $\pi$. Obviously, we discard a node if
The following rule is usually overlooked. Let \( g(\sigma_1, \sigma_2) \) be a lower bound on the cost for scheduling the jobs in \( \sigma_1 \) given the final partial schedule \( \sigma_2 \).

**Theorem 2.** The partial schedule \( \pi \) can be discarded if there exists a \( J_j \in J - \pi \) for which \( \bar{f}(J_j \pi) + g(J - \pi - J_j, \pi) \geq UB \).

**Proof.** Consider a complete sequence \( \sigma \) that has \( \pi \) as final subsequence. Thus, \( \sigma \) can be written as \( \sigma = \pi_1 J_{\pi_2} \pi \). Accordingly, we have

\[
f(\sigma) = f(\pi_1 J_{\pi_2} \pi) \geq \bar{f}(J_j \pi) + g(\pi_1 \pi_2, \pi) \geq UB.
\]

It is essential that \( g(J - \pi - J_j, \pi) \) depends only on \( \pi \) and not on \( J_j \pi \), and that we use \( \bar{f}(J_j \pi) \) instead of \( f(J_j \pi) \). We derive two corollaries from Theorem 2.

**Corollary 1.** If for a given partial schedule \( \pi \), we have that \( \bar{f}(J_j \pi) + g(J - \pi - J_j, \pi) \geq UB \) for some \( J_j \in J - \pi \) and \( J_k \in J - \pi \), then \( J_k \) precedes \( J_j \) in any complete schedule \( \sigma \pi \) with \( f(\sigma \pi) < UB \).

**Corollary 2.** The partial schedule \( \pi \) can be discarded if two jobs \( J_j \in J - \pi \) and \( J_k \in J - \pi \) exist with \( g(J - \pi - J_j, \pi) + \min\{f(J_j J_k \pi), \bar{f}(J_k J_j \pi)\} \geq UB \).

If a partial schedule \( \pi^* \neq \pi \) exists comprising the same jobs as \( \pi \) and having \( f(\sigma \pi^*) \leq f(\sigma \pi) \) for any sequence \( \sigma \) for the remaining \( n-k \) jobs, then we can also discard \( \pi \). If \( f(\sigma \pi^*) < f(\sigma \pi) \) for some \( \sigma \), then \( \pi \) is dominated by \( \pi^* \). If \( f(\sigma \pi^*) = f(\sigma \pi) \) for every \( \sigma \), then we discard either \( \pi^* \) or \( \pi \). The dominance condition above can be narrowed by the requirement that \( f(\pi^*) \leq f(\pi) \) and that the circumstances to add the remaining \( n-k \) jobs to \( \pi^* \) are at least as good as the circumstances to add the remaining jobs to \( \pi \). The question whether such a sequence \( \pi^* \) exists is of course \( \mathcal{NP} \)-complete. We strive therefore to identify sufficient conditions to discard \( \pi \). The temporary nature of the job completion times for \( \pi \) complicates the achievement of this goal. We have to be careful with dominance conditions that are based on interchange arguments: the conditions must remain valid if the jobs in \( \pi \) are deferred.

Suppose that the jobs in \( \pi \) have been reindexed in order of increasing completion times. In each of the following theorems, stating the dominance rules, the sequence \( \pi^* \) is obtained from \( \pi \) by swapping two jobs, say, \( J_j \) and \( J_k \). We do not compute the optimal completion times for the sequence \( \pi^* \). Instead, we determine the job completion times for the sequence \( \pi^* \) as follows. Let \( C_i \) and \( C_i^* \) be the completion time of \( J_i \) in the schedule \( \pi \) and \( \pi^* \), respectively. Then we let

\[
C_i^* = C_i, \quad \text{for } i = 1, \ldots, j-1, i = k+1, \ldots, |\pi|,
\]

\[
C_i^* = C_i - p_j + p_k, \quad \text{for } i = j+1, \ldots, k-1,
\]

\[
C_k^* = C_j - p_j + p_k,
\]

\[
C_j^* = C_k.
\]

Let \( F(\pi^*) \) be the cost associated with the completion times \( C_i^* \), for \( i = 1, \ldots, |\pi| \). Hence, \( F(\pi^*) \geq f(\pi^*) \). To validate the following dominance rules, we must verify that \( f(\pi) \geq F(\pi^*) \), even if the jobs are deferred. Due to the relation between \( \pi \) and \( \pi^* \), this comes down to verifying that for each set of nonnegative values \( \Delta_i \) (\( i = 1, \ldots, n \))
We start with a straightforward result.

**Theorem 3.** There is an optimal schedule with $J_j$ preceding $J_k$ if $p_j = p_k$ and $d_j \leq d_k$. $\square$

**Theorem 4.** The partial sequence $\pi$ can be discarded if there are two jobs $J_j$ and $J_k$ with $C_k = C_j + \sum_{i=j+1}^{k} p_i$, for which

$$p_j > p_k, \text{ and}$$

$$\alpha \sum_{i=j}^{k} C_i + \beta \sum_{i=j+1}^{k} \max\{0, d_i - C_i - \Delta\} \geq \alpha \sum_{i=j}^{k} C_i^* + \beta \sum_{i=j+1}^{k} \max\{0, d_i - C_i^* - \Delta\}. \tag{1}$$

**Proof.** As there is no idle time between the jobs in the block that begins with $J_j$ and ends with $J_k$, the idle time insertion algorithm will defer all jobs in this block by the same amount of time $\Delta$. Define $c(\Delta)$ as the change of cost due to the interchange, after deferring the jobs by $\Delta \geq 0$; i.e.,

$$c(\Delta) = \alpha \sum_{i=j}^{k} C_i + \beta \sum_{i=j+1}^{k} \max\{0, d_i - C_i - \Delta\} - \alpha \sum_{i=j}^{k} C_i^* + \beta \sum_{i=j+1}^{k} \max\{0, d_i - C_i^* - \Delta\}.$$  

We prove that $c(\Delta) \geq 0$ for all $\Delta \geq 0$. From condition (2), it follows immediately that $c(0) \geq 0$. Furthermore, $C_j < C_j^*$ implies $\max\{0, d_j - C_j - \Delta\} \geq \max\{0, d_j - C_j^* - \Delta\}$ for all $\Delta \geq 0$; $C_i > C_i^*$ for $i = j+1, \ldots, k$ implies $\max\{0, d_i - C_i - \Delta\} \geq \max\{0, d_i - C_i^* - \Delta\} \geq \max\{0, d_i - C_i - \Delta\} - \max\{0, d_i - C_i^* - \Delta\}$ for all $\Delta \geq 0$. Combining the inequalities, we get the desired result. $\square$

The possible increase of $E_j$ is excluded here. The following theorem shows that in case no idle time exists between two adjacent jobs, then dominance already exists if condition (1) is satisfied for $\Delta = 0$.

**Theorem 5.** The partial sequence $\pi$ can be discarded if there are two jobs $J_j$ and $J_k$ with $C_k = C_j + p_k$, for which

$$p_j > p_k,$$

and

$$\alpha (p_j - p_k) + \beta \max\{0, d_j - C_j\} + \beta \max\{0, d_k - C_k\} \geq$$

$$\beta \max\{0, d_j - C_k\} + \beta \max\{0, d_k - C_k + p_j\}. \tag{3}$$

**Proof.** Define $c(\Delta)$ as the change of cost due to the interchange, after deferring the jobs by $\Delta \geq 0$; i.e.,

$$c(\Delta) = \alpha (p_j - p_k) + \beta \max\{0, d_j - C_j - \Delta\} - \beta \max\{0, d_j - C_k - \Delta\} +$$

$$\beta \max\{0, d_k - C_k - \Delta\} - \beta \max\{0, d_k - C_k + p_j - \Delta\}.$$
We need to show that condition (3), stating that \( c(0) > 0 \), implies \( c(\Delta) \geq 0 \) for all \( \Delta \geq 0 \). Note that \( \alpha < \beta \) implies that at least one due date is smaller than \( C_k \); otherwise, condition (3) is not valid.

The expression \( c(\Delta) \) has three components. The first component is \( \alpha(p_j - p_k) \); it is a constant. The second component is \( \beta \max\{0, d_j - C_j - \Delta\} - \beta \max\{0, d_j - C_k - p_j - \Delta\} \); it is a piecewise linear function of \( \Delta \). The function value is \( \beta p_j \) if \( d_j \geq C_k + \Delta \), and 0 if \( d_j \leq C_j + \Delta \). If \( C_k + \Delta > d_j \geq C_j + \Delta \), then the gradient is \(-1\). The third component is \( \beta \max\{0, d_k - C_k - \Delta\} - \beta \max\{0, d_k - C_k + p_j - \Delta\} \); it is also a piecewise linear function of \( \Delta \). The function value is \(-\beta p_j \) if \( d_k \geq C_k + \Delta \), and 0 for \( d_k \leq C_k - p_j + \Delta \). The gradient is \( 1 \) if \( C_k + \Delta > d_k \geq C_k - p_j + \Delta \). Combining the three components yields a piecewise linear function whose behavior depends on the due dates. We now make the following observations. First, \( c(\Delta) > 0 \) if \( \Delta \geq d_k - C_k + p_j \). Second, if \( c(t) > 0 \) for some \( t \geq d_k - C_k \), then \( c(\Delta) > 0 \) for all \( \Delta \geq t \). As at least one due date is smaller than \( C_k \), the second observation implies that, if \( d_k \leq d_j \), then \( c(\Delta) > 0 \) for all \( \Delta \geq 0 \).

The only case left to consider is \( d_j < d_k \) and \( 0 \leq \Delta \leq d_k - C_k \). Then, we have \( c(\Delta) = \alpha(p_j - p_k) - \beta p_j + \beta \max\{0, d_j - C_j - \Delta\} \). As \( d_j - C_j - \Delta \leq d_j - C_j = d_j - C_k + p_k \leq p_k \), we get \( c(0) \leq (\alpha - \beta)(p_j - p_k) \leq 0 \), which contradicts the assumption. This completes the proof. \( \square \)

In Corollary 3, explicit conditions for the existence of dominance are derived from Theorem 5. This corollary is referred to when lower bounds are discussed in Section 4.

**Corollary 3.** The partial sequence \( \pi \) can be discarded if there are two jobs \( J_j \) and \( J_k \) with \( C_k = C_j + p_k \) such that

\[ p_j > p_k, \]

and one of the following conditions is satisfied:

\[ C_k - p_j \geq d_k, \]
\[ C_k - p_j < d_k, C_k \geq d_k, \alpha(p_j - p_k) \geq \beta(d_k - C_k + p_j), \]
\[ C_k - p_j < d_k, C_k < d_k, \alpha(p_j - p_k) \geq \beta p_j, \]
\[ C_k - p_j < d_k, C_k \geq d_k, \alpha(p_j - p_k) \geq \beta(d_k - d_j - p_k + p_j). \]

**Theorem 6.** The partial sequence \( \pi \) with \( J_k \) scheduled last is dominated if there is a \( J_j \) such that

\[ p_j > p_k, \text{ and } C_j - p_j + p_k \geq d_k. \]

**Proof.** Let \( \pi = \pi_1 J_j \pi_2 J_k \pi_3 J_j \) and \( \pi^* = \pi_1 J_k \pi_2 J_j \). We compute the effect of the interchange on the scheduling cost. Since \( J_k \) is the last job in the optimal schedule \( \pi \), we have \( C_k \geq d_k \). In addition, we know \( C_j^* = \max\{d_j, C_k - p_k + p_j\} \) and \( C_k^* = C_j - p_j + p_k \geq d_k \). First, suppose \( C_j^* = d_j \). The effect of the interchange is then equal to

\[ \alpha(C_j + C_k - (C_j - p_j + p_k) - d_j) + \beta(d_j - C_j) \geq \alpha(C_j - p_j + p_k - d_j) + \alpha(d_j - C_j) > 0, \]

as \( C_k - p_k \geq C_j \). Second, suppose that \( C_j^* = C_k - p_k + p_j \). The effect of the interchange is then equal to

\[ \alpha(C_j + C_k - (C_k - p_k + p_j) - (C_j - p_j + p_k)) + \beta \max\{0, d_j - C_j\} \geq 0. \]

The effect remains non-negative if the jobs are deferred. \( \square \)
Theorem 7. There is an optimal schedule in which $J_k$ is not scheduled in the last position, if there is some $J_j$ with $p_j > p_k$ and $d_j - p_j > d_k - p_k$.

Proof. We let $\pi = \pi_1 J_j \pi_2 J_k$ and $\pi^* = \pi_1 J_k \pi_2 J_j$ and compute the effect of the interchange. We have $C_k \geq d_k$ and $C_k - p_k \geq C_j$; in addition, we define here $C_j^* = \max\{d_j, C_k - p_k + p_j\}$. The effect of the interchange has to be non-negative; we therefore have to prove that

$$\alpha C_k + \beta \max\{0, d_j - C_j\} \geq \alpha(p_k - p_j + C_j^*) + \beta \max\{0, d_k - p_k + p_j - C_j\}. \quad (4)$$

First, we examine the case $C_j^* = C_k - p_k + p_j$. Expression (4) is then equivalent to

$$\beta \max\{0, d_j - C_j\} \geq \beta \max\{0, d_k - p_k + p_j - C_j\},$$

which is true for any $C_j$ since $d_j - p_j \geq d_k - p_k$. Second, consider the case $C_j^* = d_j$. This implies $d_j > C_j$, since $d_j \geq C_k - p_k + p_j > C_j - p_k + p_j > C_j$. Hence, expression (4) is equivalent to

$$\alpha C_k + \beta (d_j - C_j) \geq \alpha(p_k - p_j + d_j) + \beta \max\{0, d_k - p_k + p_j - C_j\}.$$ 

Suppose $\max\{0, d_k - p_k + p_j - C_j\} = d_k - p_k + p_j - C_j$. We must then verify that

$$\alpha C_k + \beta d_j \geq \alpha(d_j - p_j + p_j) + \beta(d_k - p_k + p_j).$$

As $C_k \geq d_k$, we only need to prove that

$$0 \geq (\alpha - \beta)(d_j - p_j - (d_k - p_k));$$

this expression is true since $\beta > \alpha$ and $d_j - p_j \geq d_k - p_k$. Conversely, suppose $\max\{0, d_k - p_k + p_j - C_j\} = 0$. Since $\alpha C_k + \beta (d_j - C_j) \geq \alpha(C_k + d_j - C_j) \geq \alpha(p_k + d_j) > \alpha(p_k - p_j + d_j)$, expression (4) is also true for this case. \(\square\)

Corollary 4. There is an optimal schedule in which $J_j$ is scheduled last if $p_j \geq p_k$ and $d_j - p_j \geq d_k - p_k$ for each $J_k \in J$. \(\square\)

4. Lower bounds

In this section, we present five lower bound procedures. It seems to be impossible to develop a lower bound procedure that copes satisfactorily with all conceivable due date patterns. For example, imagine an instance with due dates small with respect to the sum of the processing times; little idle time needs then to be inserted. In contrast, consider an instance with $d_k \sum_{j=1}^n p_j$ for each $J_k$; the machine will then be idle for some time before processing the first job. Numerous variations and combinations of both patterns are possible.

Each of the lower bound methods is effective for a specific class of instances. Nonetheless, we use them supplementary rather than complementary. We partition the job set $J$ into subsets, apply each lower bound method to each subset, and aggregate the best lower bounds. In this way, we hope to obtain a lower bound that is stronger than the separate lower bounds obtained for the entire set $J$. The success of this strategy depends on the partitioning strategy. The jobs in a subset should be conflicting, that is, they should overlap when completed at their due date. If they are not, then we get the weak lower bound $\alpha \sum_{j=1}^n d_j$. In this sense, we prefer subsets such that the executions of the jobs in the same subset interfere with each other, but not with the execution of the jobs in the other subsets. We propose two partitioning strategies that pursue this effect.
The first strategy is motivated by the structure of any optimal schedule. The jobs that are consecutively processed between two periods of idle time interfere with each other, but not with the other jobs. Such a partitioning is hard to obtain. To mimic such a partitioning, we identify clusters. A cluster is a set of jobs such that for each job $J_j$ in the cluster there is another job $J_k$ in the cluster such that the intervals $[d_j-p_j, d_j]$ and $[d_k-p_k, d_k]$ overlap; hence, for each job in the cluster there exists a conflict with at least one other job in the cluster. However, clusters may interfere with each other in any optimal schedule.

The second strategy is the following. Given a partial schedule $\pi$, we try to identify the jobs not in $\pi$ that will be early in any optimal complete schedule of the form $\sigma \pi$. We call these jobs surely early. The idea is to derive an upper bound $T$ on the completion times of the unscheduled jobs; accordingly, $J_j \in \pi \pi$ is surely early if $d_j > T$. For instance, let $g$ be the primitive directional derivative for deferring the first job in $\pi$ by one unit. Suppose that $|\pi \pi| (\beta - \alpha) \leq g$. The current set of completion times for the jobs in $\pi$ is then optimal for any schedule $\sigma \pi$; an upper bound $T$ is then the start time of the first job in $\pi$. Other upper bounds are derived from the dominance rules. Suppose $J_j$ and $J_k$ are adjacent in $\pi$ with $p_j > p_k$ and $J_j$ preceding $J_k$. (It is not necessary that $C_k = C_j + P_k$.) The first condition of Corollary 3 indicates that $\pi$ is dominated if $C_k \geq d_k + p_j$; hence, an upper bound is given by $d_k + p_j - 1 - \Sigma J_j \in \pi, c; \Sigma P_l$. From the other criteria in Corollary 3 and from Theorem 7, similar upper bounds are derived. They can also be derived from Theorem 4, but this requires an intricate procedure. Finally, we set $T$ equal to the minimum of all upper bounds. If no upper bound is specified, then we let $T = \infty$.

4.1. First method: relax the objective function

Let $\mathcal{E}$ denote the set of surely early jobs; let $\mathcal{R}$ be the set of remaining jobs. Observe that
\[
\min_{\sigma \in \Omega} \sigma \mathcal{f}(\sigma) \geq \min_{\sigma \in \Omega} \sum_{J_j \in \mathcal{R}} \alpha C_j + \min_{\sigma \in \Omega} \sum_{J_j \in \mathcal{E}} [\alpha C_j + \beta E_j],
\]
where $\Omega_{\mathcal{R}}$ and $\Omega_{\mathcal{E}}$ denote the set of feasible schedules for the jobs in $\mathcal{R}$ and $\mathcal{E}$. The problem of minimizing $\Sigma J_j \in \mathcal{E} [\alpha C_j + \beta E_j]$ is solvable in polynomial time; we have $E_j = d_j - C_j$ for each $J_j \in \mathcal{E}$, and hence, the scheduling cost reduces to $\Sigma J_j \in \mathcal{E} [(\alpha - \beta) C_j + \beta d_j]$. Applying an analogon of Smith’s rule (Smith, 1956), we minimize this cost component by scheduling the jobs in $\mathcal{E}$ in the interval $[T - p(\mathcal{E}), T]$ in order of non-increasing processing times; the correctness of this rule is easily verified by an interchange argument. The other subproblem is solved by Smith’s rule: simply schedule the jobs in $\mathcal{R}$ in non-decreasing order of their processing times in the interval $[0, p(\mathcal{R})]$. In the example, $\mathcal{E} = \varnothing$, and the lower bound is $21 \alpha$.

A slight improvement of the lower bound is possible. Let $E_{\max}^*$ be the minimum maximum earliness for the jobs in $\mathcal{R}$ if they are processed in the interval $[0, p(\mathcal{R})]$. We compute $E_{\max}^*$ from the minimum-slack-time sequence, that is, the sequence in which the jobs appear in order of non-decreasing values $d_j - p_j$. Avoiding $E_{\max}^*$ requires at least $E_{\max}^*$ units of machine idle time. The lower bound can therefore be improved by $\alpha E_{\max}^*$. If we have stored the shortest-processing-time sequence and the minimum-slack-time sequence, then we compute this lower bound in $O(n)$ time per node. In the example, we have $E_{\max}^* = 4$; hence, the lower bound is $25 \alpha$. This lower bound approach can only be applied in conjunction with Theorem 2 if $\mathcal{E} = \varnothing$.

Since all jobs in $\mathcal{R}$ are scheduled in the interval $[0, p(\mathcal{R})]$, and since only one early job in $\mathcal{R}$ is taken into account, this lower bound is only effective if the due dates are small relative to the sum of the processing times.
4.2. Second method: relax the machine capacity

Recall that we write the objective function alternatively as \( f(\sigma) = (\beta - \alpha)\sum_{j=1}^n E_j + \alpha \sum_{j=1}^n T_j + \alpha \sum_{j=1}^n d_j \) for each \( \sigma \in \Omega \). Since the job earliness and tardinesses are non-negative by definition, we have that \( f(\sigma) \geq \alpha \sum_{j=1}^n d_j \) for each \( \sigma \in \Omega \).

We gain more insight if we derive this bound in the following way. Suppose that the machine can process an infinite number of jobs at the same time; this is a relaxation of the limited capacity of the machine. As \( \alpha < \beta \), the optimal schedule has \( C_j = d_j \) for each \( J_j \); this gives rise to the lower bound \( \alpha \sum_{j=1}^n d_j \). If no jobs overlap in their execution, then this schedule is feasible and hence optimal for the original problem. For the example, this relaxation gives the lower bound 35\( \delta \). The corresponding schedule is not feasible; \( J_2 \) and \( J_3 \) overlap in their execution (see Figure 2).

![Figure 2. Gantt chart for machine with infinite capacity.](image)

This conflict can be settled by executing \( J_3 \) before \( J_2 \), or, conversely, \( J_2 \) before \( J_3 \). If we intend to schedule \( J_2 \) after \( J_3 \), then we have basically two options: we retain either the completion time of \( J_3 \) or the completion time of \( J_2 \). For the first option, the additional cost is 3\( \gamma \); for the second option, the additional cost is 3(\( \beta - \alpha \)). Executing \( J_2 \) after \( J_3 \) costs therefore at least 3\( \gamma \) extra, where \( \gamma = \min(\alpha, \beta - \alpha) \). Similarly, we find that executing \( J_3 \) after \( J_2 \) costs 6\( \gamma \) extra. Hence, the minimum additional cost required to settle the overlap is \( \min(3\gamma, 6\gamma) = 3\gamma \). Accordingly, an improved lower bound is 38\( \delta \).

We now describe a general procedure to improve the lower bound \( \alpha \sum_{j=1}^n d_j \) by taking the overlap between jobs into consideration. Overlap of \( J_j \) and \( J_k \) (\( J_j \neq J_k \)) occurs if the intervals \([d_j - p_j, d_j]\) and \([d_k - p_k, d_k]\) overlap. Let \( c_{jk} = \max \{0, d_j - (d_k - p_k)\} \) denote the additional cost to execute \( J_j \) immediately before \( J_k \); let \( \sigma(i) = j \) denote that \( J_j \) occupies the \( i \)-th position in the sequence \( \sigma \). For any optimal schedule \( \sigma \), we have that \( f(\sigma) \geq \alpha \sum_{j=1}^n d_j + \sum_{j=1}^n c_{\sigma(j)\sigma(j+1)} \); the last term is the length of the Hamiltonian path \( \sigma(1) \cdots \sigma(n) \). The following procedure shows that the Hamiltonian path problem is solvable in \( O(n \log n) \) time.

Partition the set of jobs into a set of clusters \( Q_1, \ldots, Q_m \) as described above. Let \( HP_l \) be the shortest Hamiltonian path for \( Q_l \), and let \( c(HP_l) \) denote its length. We have \( c(HP_l) = \min_{c(\pi) - \max_{l, l' \in Q_l, l \neq l'} c_{l,l'}} \), for each \( l (l = 1, \ldots, m) \). We have also \( \sum_{j=1}^n c_{\pi(j)\pi(j+1)} \geq \sum_{j=1}^n c(HP_l) \) for any sequence \( \pi \), as can be easily verified. The individual Hamiltonian paths can be combined into one Hamiltonian path of length no more than the sum of the lengths of the separate paths.

4.3. Third method: relax the due dates

4.3.1. The common due date problem

Suppose the due dates have been replaced by a due date \( d \) common to all jobs. Consider the following common due date problem: for a given \( d \), determine a schedule that minimizes...
\[(\beta - \alpha) \sum_{j=1}^{n} E_j + \alpha \sum_{j=1}^{n} T_j + \alpha nd - \beta \sum_{j=1}^{n} \max\{0, d - d_j\}. \]  

(CD)

For any \(d\), the optimal solution value is a lower bound for the original problem, since

\[f(\sigma) = \alpha \sum_{j=1}^{n} C_j + \beta \sum_{j=1}^{n} \max\{0, d - C_j\} \geq \alpha \sum_{j=1}^{n} C_j + \beta \sum_{j=1}^{n} \max\{0, d - C_j\} - \beta \sum_{j=1}^{n} \max\{0, d - d_j\} \]

\[= (\beta - \alpha) \sum_{j=1}^{n} E_j + \alpha \sum_{j=1}^{n} T_j + \alpha nd - \beta \sum_{j=1}^{n} \max\{0, d - d_j\}. \]

There are two issues involved: (i) how to solve problem (CD)?, and (ii) how to find the value \(d\) maximizing the lower bound?

Problem (CD) consists of two parts. The first part is the problem of minimizing \( (\beta - \alpha) \sum_{j=1}^{n} E_j + \alpha \sum_{j=1}^{n} T_j \). If the machine is only available from time 0 onwards and if \(d\) is given, then this problem is \#P-hard (Hall, Kubiak, and Sethi, 1991; Hoogeveen and Van de Velde, 1991). However, a strong lower bound \(L(d)\) is derived by applying Lagrangian relaxation (see Hoogeveen, Oosterhout, and Van de Velde, 1990). The second part is the problem of maximizing the function \(G: d \to \alpha nd - \beta \sum_{j=1}^{n} \max\{0, d - d_j\}\); this problem is solvable in polynomial time. Rather than solving problem (CD) to optimality and finding the best \(d\), we maximize the lower bound \(L(d) + G(d)\) over \(d\).

First, we derive the best Lagrangian lower bound \(L(d)\) for a given \(d\). The derivation proceeds without details; we refer to Hoogeveen, Oosterhout, and van de Velde (1990) for an elaborate treatment. Let \(E\) denote the set of jobs that are not tardy. Since the machine is only available from time 0 onwards, we have the condition that \(p(E) \leq d\). We dualize this condition by use of the Lagrangian multiplier \(\lambda \geq 0\). For a given \(\lambda \geq 0\), the Lagrangian problem is then to find \(L(d, \lambda)\), which is the minimum of \( (\beta - \alpha) \sum_{j=1}^{n} E_j + \alpha \sum_{j=1}^{n} T_j + \lambda p(E) - \lambda d \).

The Lagrangian problem is solvable in polynomial time by Emmons’s matching algorithm (Emmons, 1987), which proceeds by the concept of positional weights. Straightforward arguments show that there exists an optimal schedule with some job completed exactly on its due date. The weights for the early positions are then \(\lambda, \lambda + (\beta - \alpha), \lambda + 2(\beta - \alpha), \ldots, \lambda + (n-1)(\beta - \alpha)\); the smallest weight is for the first position in the schedule. The weights for the tardy positions are \(\alpha, 2\alpha, \ldots, n\alpha\); the smallest weight is for the last position in the schedule. Emmons’s matching algorithm assigns the job with the \(j\)th largest processing time to the position with the \(j\)th smallest weight, for \(j = 1, \ldots, n\). Ties are settled to minimize the amount of work before \(d\). Let \(\sigma_\lambda\) be the optimal schedule for the Lagrangian problem, and let \(W(\sigma_\lambda)\) be the amount of work before \(d\) in \(\sigma_\lambda\).
The best Lagrangian lower bound \( L(d) \) is found as

\[
L(d) = \max \{ L(d, \lambda) \mid \lambda \geq 0 \}.
\]

Due to the integrality of \( \alpha \) and \( \beta \), the optimization over \( \lambda \geq 0 \) may be reduced to the optimization over \( \lambda \in \mathbb{N}_0 \). The optimal choice for \( \lambda \) can be shown to be such that \( W(\sigma_{\lambda-1}) \geq d \geq W(\sigma_{\lambda}) \); this choice gives us the Lagrangian lower bound \( L(d) \).

We are now able to characterize the function \( L : d \to L(d) \). The function \( L \) is continuous and piecewise linear; the value \( L(d) \) depends on \( d \) only through the choice for \( \lambda \). Hence, there are at most \( \min\{n^2, na\} \) breakpoints: they correspond to the values \( d = W(\sigma_\lambda) \), for \( \lambda = 0, 1, \ldots, na \). The derivative of the trade-off curve between two consecutive breakpoints, the first corresponding to \( W(\sigma_\lambda) \), is equal to \(-\lambda\).

The function \( G : d \to \alpha nd - \beta \sum_{j=1}^{n} \max\{0, d-d_j\} \) is also continuous and piecewise linear; the breakpoints correspond to the values \( d = d_j \), for \( j = 1, \ldots, n \). The lower bound \( L(d)+G(d) \) is therefore also continuous and piecewise linear in \( d \); the value \( d \) maximizing this lower bound is found at a breakpoint.

For any given \( d \), \( L(d) \) is determined in \( O(n \log n) \) time. The function \( L \) has \( O(\min\{n^2, na\}) \) breakpoints; the corresponding values are computed in \( O(n^2) \) time. (Every new breakpoint is derived from the previous one by interchanging some jobs, which requires only constant time, and only \( O(n^2) \) interchanges are needed to find all breakpoints.) The function \( G \) has \( O(n) \) breakpoints. Hence, maximizing \( L(d)+G(d) \) over \( d \) is achieved in \( O(n^2) \) time.

In our 3-job example, we have \( d = 10 \). For the positions after \( d \), the weights are 1,2, and 3; for the positions before \( d \), the weights are 0, 3, and 6. An optimal schedule is depicted in Figure 3. Its objective value is 39\( \alpha \); this happens to be the optimal solution value for the original problem.

\[
\begin{array}{c|c|c|c}
J_3 & J_2 & J_1 \\
0 & d & 13 & 16
\end{array}
\]

**Figure 3.** Optimal schedule for the common due date problem.

In a node of the search tree, there are two ways to implement this lower bound procedure. Let \( \pi = \pi_1 \pi_2 \) be the partial schedule associated with the node. Disregarding \( \pi \), we get the lower bound \( f(\pi) + c(\tilde{J}-\pi) \), where \( c(\tilde{J}-\pi) \) denotes the optimal solution value for the common due date problem for the jobs in \( \tilde{J}-\pi \). However, if \( \pi_1 \) and the optimal schedule for the common due date problem overlap in their execution, then it makes sense to take \( \pi_1 \) into regard. We do this in the following way. First of all, we require that \( d \) is common to each \( J_i \pi_2 \). Subsequently, we solve the common due date problem under the condition that the jobs in \( \pi_1 \) retain their positions. Given the set of positions, it is easy to construct an optimal schedule: assign the jobs in \( \pi_1 \) to the last \( |\pi_1| \) positions, and assign the other jobs to the remaining positions according to Emmons's algorithm. Lemma 1 states that we may use the same set of positions as for the case \( \pi_1 = \emptyset \).

**Lemma 1.** The optimal schedule for the common due date problem with the last \( |\pi_1| \) jobs fixed occupies the \( n \) positions with least positional weights, where \( n = n - |\pi_2| \).
Proof. Suppose to the contrary that the optimal schedule $\sigma$ for the jobs $J_j \pi_2$ does not occupy the $n$ positions with least positional weights. Let $n_1$ jobs in $\sigma$ be early or just-in-time and let $n_2 = \overline{n} - n_1$ jobs in $\sigma$ be tardy. Suppose the set of optimal weights corresponds to $\overline{n}_1$ positions before $d$, and to $\overline{n}_2 = \overline{n} - \overline{n}_1$ positions after $d$. Suppose $n_1 < \overline{n}_1$. We then transfer the job occupying the $n_2$th tardy position in $\sigma$ (the first tardy job) to the $(n_1 + 1)$th early position. The latter position is in the optimal set; the former is not. Hence, this transfer reduces the objective value, thereby contradicting the optimality of $\sigma$. If $n_1 > \overline{n}_1$, then a similar argument applies.

The common due date lower bound can only be used in conjunction with Theorem 2 if the lower bound is independent from the partial sequence $j_\pi$. It is effective if the due dates are close to each other.

4.3.2. The common slack time problem
Consider the special case of the $1 | \alpha \Sigma C_j + \beta \Sigma E_j$ problem where all jobs have equal slack time $s$; i.e., $d_j - p_j = s$ for each $J_j (j = 1, \ldots, n)$. This problem has the same features as the common due date problem. The best Lagrangian lower bound is also computed in $O(n \min \{\alpha, n\})$ time; there are the same options to implement the lower bound. The common slack time lower bound is effective if all slack times are close to each other.

4.4. Fourth method: relax the processing times
Again, we consider a special case of the $1 | \alpha \Sigma C_j + \beta \Sigma E_j$ problem. Assume that all processing times are equal. Theorem 3 indicates that the earliest-due-date sequence (i.e., the sequence with the jobs in order of non-decreasing due dates) is optimal. This special case is solved in $O(n^2)$ time, which is needed to compute the optimal schedule for a given sequence.

Let us return to our original problem. Define $p_{\min} = \min_{1 \leq j \leq n} p_j$. The optimal solution value of the relaxed problem $1 | p_j = p_{\min} | \alpha \Sigma C_j + \beta \Sigma E_j$ provides a lower bound for the original problem: each set of job completion times that is feasible for the original problem is also feasible for the relaxed problem and has equal cost.

Given a partial schedule $\pi$, let $\sigma$ be the earliest-due-date sequence for the jobs in $\pi$, and let $g(\sigma)$ be the optimal solution value for the relaxed problem. Disregarding $\pi$, we get the lower bound $f(\pi) + g(\sigma)$. We can marginally improve on this lower bound. Suppose we have reindexed the jobs in order of non-decreasing due dates. Corollary 4 indicates that $J_n$ is also scheduled last if we put its processing time equal to $\min \{p_n, p_{\min} + d_n - d_{n-1}\}$. An improved lower bound is therefore given by $f(\pi) + g(\sigma) + \alpha [\min \{p_n, p_{\min} + d_n - d_{n-1}\} - p_{\min}]$.

If the execution of jobs in $\sigma$ overlap with the execution of jobs in $\pi$, then it pays to take $\pi$ into account. The lower bound is then equal to the cost for the sequence $\sigma \pi$ with the jobs in $\pi$ still having their original processing times.

Both bounds are computed in $O(n^2)$ time and dominate the lower bound $\alpha \Sigma_{j=1}^n d_j$. Only the first version can be used in conjunction with Theorem 2. The common processing time lower bounds are only effective if the processing times are close to each other.

In our 3-job example, we have $p_{\min} = 3$, $d_1 = 15$, and $d_2 = d_3 = 10$. An optimal schedule for the common processing time problem is depicted in Figure 4. Its objective value is $39\alpha$; this is equal to the optimal solution value for the original problem.
4.5. Fifth method: Lagrangian relaxation

The problem of minimizing total inventory cost, referred to as problem (P), can be formulated as follows. Determine values $C_j$ and $E_j$ ($j = 1, \ldots, n$) that minimize

$$\alpha \sum_{j=1}^{n} C_j + \beta \sum_{j=1}^{n} E_j$$

subject to

$$E_j \geq 0, \quad \text{for } j = 1, \ldots, n,$$  

$$E_j \geq d_j - C_j, \quad \text{for } j = 1, \ldots, n,$$  

$$C_j \geq C_k + p_j \text{ or } C_k \geq C_j + p_k, \quad \text{for } j, k = 1, \ldots, n, j \neq k,$$  

$$C_j - p_j \geq 0, \quad \text{for } j = 1, \ldots, n.$$  

The conditions (5) and (6) reflect the definition of job earliness, while the conditions (7) ensure that the machine executes at most one job at a time. The conditions (8) express that the machine is available only from time 0 onwards.

We introduce a non-negative vector $\lambda = (\lambda_1, \ldots, \lambda_n)$ of Lagrangian multipliers in order to dualize the conditions (5). For a given vector $\lambda \geq 0$, the Lagrangian problem is to determine the value $L(\lambda)$, which is the minimum of

$$\alpha \sum_{j=1}^{n} C_j + \beta \sum_{j=1}^{n} (\beta - \lambda_j)E_j$$

subject to the conditions (6), (7), and (8). We know that for any given $\lambda \geq 0$ the value $L(\lambda)$ provides a lower bound to problem (P). If $\beta - \lambda_j < 0$ for some $j$, we get $E_j = \infty$, which disqualifies the lower bound. We therefore assume that

$$\lambda_j \leq \beta, \quad \text{for } j = 1, \ldots, n. \tag{9}$$

This, in turn, implies that, for any solution to the Lagrangian problem, conditions (6) hold with equality: $E_j = d_j - C_j$ for each $j (j = 1, \ldots, n)$. Hence, the Lagrangian problem, referred to as problem (L$_{\lambda}$), transforms into the problem of minimizing

$$\sum_{j=1}^{n} (\alpha - \beta + \lambda_j)C_j + \sum_{j=1}^{n} (\beta - \lambda_j)d_j$$

subject to
\[ C_j \geq C_k + p_j \text{ or } C_k \geq C_j + p_k, \text{ for } j, k = 1, \ldots, n, j \neq k, \]  
\[ C_j - p_j \geq 0, \text{ for } j = 1, \ldots, n. \]  
\[ \text{If } \alpha - \beta + \lambda_j < 0 \text{ for some } J_j, \text{ we get } C_j = \infty, \text{ which makes the lower bound rather weak. However, as } \] 
demonstrated at the beginning of Section 4, we can determine an upper bound \( T \) on the job completion times, which implies that 
\[ C_j \leq T, \text{ for } j = 1, \ldots, n. \]  
Although the conditions (10) are redundant for the primal problem (P), they are essential to admit values \( \lambda_j < \beta - \alpha \). For solving problem \((L_\lambda)\) under these additional conditions, we first determine the sets of jobs \( \mathcal{S} = \{ J_j | \lambda_j > \beta - \alpha \} \), \( \mathcal{S} = \{ J_j | \lambda_j < \beta - \alpha \} \), and \( \mathcal{S} = \{ J_j | \lambda_j = \beta - \alpha \} \). The following theorem stipulates that problem \((L_\lambda)\) is solved by a simple extension of Smith's rule (Smith, 1956) for solving the \( 1 | \Sigma w_j C_j \) problem; the proof proceeds by an elementary interchange argument.

**Theorem 9.** Problem \((L_\lambda)\) with the additional conditions (10) is solved by scheduling the jobs in \( \mathcal{S} \) in non-increasing order of ratios \( (\alpha - \beta + \lambda_j)/p_j \) in the interval \([0, p(\mathcal{S})]\), and scheduling the jobs in \( \mathcal{S} \) in non-increasing order of ratios \( (\alpha - \beta + \lambda_j)/p_j \) in the interval \([T - p(\mathcal{S}), T]\). The remaining jobs can be scheduled in any order in the interval \([p(\mathcal{S}), T - p(\mathcal{S})]\). □

We are interested in determining the vector \( \lambda^* = (\lambda_1^*, \ldots, \lambda_n^*) \) of Lagrangian multipliers that induces the best Lagrangian lower bound. The vector \( \lambda^* \) stems from solving the Lagrangian dual problem, referred to as problem (D): maximize 

\[ L(\lambda) \] 
subject to 

\[ 0 \leq \lambda_j \leq \beta, \text{ for } j = 1, \ldots, n. \]  

Problem (D) is solvable to optimality in polynomial time by use of the ellipsoid method; see Van de Velde (1991). Since the ellipsoid method is very slow in practice, we take our resort to an approximation algorithm for problem (D).

First, we identify the primitive directional derivatives. In the solution to the Lagrangian problem \((L_\lambda)\), the position of \( J_j \) depends on the ratio \( (\alpha - \beta + \lambda_j)/p_j \); we call this ratio the relative weight of \( J_j \). The larger this relative weight, the smaller the completion time of \( J_j \). If other jobs have precisely the same relative weight as \( J_j \), then the exact position of \( J_j \) is determined by settling ties. Let now \( C^+_j(\lambda) \) denote the earliest possible completion time of \( J_j \) in an optimal schedule for problem \((L_\lambda)\); let \( C^+_j(\lambda) \) denote the latest possible completion time of \( J_j \) in an optimal schedule for problem \((L_\lambda)\). If we increase \( \lambda_j \) by \( \epsilon > 0 \), then we can choose \( \epsilon \) small enough to make sure that at least one optimal schedule for problem \((L_\lambda)\) remains optimal; for a proof, see Van de Velde (1991). In fact, all such optimal schedules must have \( J_j \) completed on time \( C^+_j(\lambda) \). If we increase \( \lambda_j \) by such a sufficiently small \( \epsilon > 0 \), then the Lagrangian objective value is affected by \( \epsilon (C^+_j(\lambda) - d_j) \). The primitive directional derivative for increasing \( \lambda_j \), as denoted by \( I^+_j(\lambda) \), is therefore simply 

\[ I^+_j(\lambda) = C^+_j(\lambda) - d_j, \text{ for } j = 1, \ldots, n. \]  

Hence, if \( I^+_j(\lambda) > 0 \), then increasing \( \lambda_j \) is an ascent direction: we get an improved lower bound by moving some scalar step size along this direction. In a similar fashion, we derive that the primitive directional derivative for decreasing \( \lambda_j \), denoted by \( I^-_j(\lambda) \), is
\[ l_j^*(\lambda) = d_j - C_j^*(\lambda), \quad \text{for } j = 1, \ldots, n. \]

If \( l_j^*(\lambda) > 0 \), then decreasing \( \lambda_j \) is an ascent direction. Note that directional derivatives may not exist at the boundaries of the feasible region of \( \lambda \); for instance, \( l_j^*(\lambda) \) is undefined for \( \lambda = (0, \ldots, 0) \), for any \( i = 1, \ldots, m \).

Second, we determine an appropriate step size \( \Delta > 0 \) to move by along a chosen ascent direction. We compute the step size that takes us to the first point where the corresponding primitive directional derivative is no longer positive. If no such point exists, then we choose the step size as large as possible while maintaining feasibility.

Suppose \( l_j^*(\lambda) > 0 \): \( J_j \) is tardy in any optimal schedule for problem (L\(_A\)). Increasing \( \lambda_j \), thereby putting \( J_j \) earlier in the schedule, is an ascent direction. We distinguish the cases \( p_j - d_j > 0 \), \( p_j - d_j = 0 \), and \( p_j - d_j < 0 \). Consider the case \( p_j - d_j > 0 \). Hence, \( J_j \) is unavoidably tardy, and \( l_j^*(\lambda) > 0 \) for all \( \lambda \geq 0 \) with \( \lambda_j \leq \beta \). Therefore, we take the step size \( \Delta = \beta - \lambda_j \). Accordingly, we must also have that \( \lambda_j^* = \beta \); otherwise, increasing \( \lambda_j^* \) would be an ascent direction. If \( p_j = d_j \), then there exists an optimal solution to problem (D) with \( \lambda_j^* = \beta \). Find \( T = \{ J_j \mid p_j \geq d_j \} \). We have proven the following result.

**Theorem 10.** There exists an optimal solution for the Lagrangian dual problem (D) with \( \lambda_j^* = \beta \) for each \( J_j \in T \). □

Suppose now \( p_j < d_j \). The step size \( \Delta \) must satisfy \( \lambda_j + \Delta \leq \beta \). We identify the first job in the schedule, say, \( J_k \), for which \( C_k - p_k + p_j \leq d_j \). Since \( p_j < d_j \), such a \( J_k \) always exists. If \( J_j \) is scheduled in \( J_k \)'s position, then \( J_j \) is not tardy. Hence, if there were no upper bound on \( \lambda \), then increasing \( \lambda_j \) would be an ascent direction up to the point where the relative weight of \( J_j \) becomes equal to the relative weight of \( J_k \). Hence, the maximum step size along this ascent direction is the largest value \( \Delta \) such that

\[
(\alpha - \beta + \lambda_j + \Delta)/p_j \leq (\alpha - \beta + \lambda_k)/p_k \quad \text{and} \quad 
\lambda_j + \Delta \leq \beta.
\]

Let now \( \lambda = (\lambda_1, \ldots, \lambda_j + \Delta, \ldots, \lambda_n) \). Suppose \( \lambda_j + \Delta < \beta_j \). Since the relative weights for all jobs but \( J_j \) have remained the same, optimal solutions for the problems (L\(_\lambda\)) and (L\(_T\)) exist with the same jobs scheduled before \( J_k \). Now \( J_j \) and \( J_k \) have equal relative weights: in any optimal solution to problem (L\(_\lambda\)), \( J_j \) can be scheduled before \( J_k \) or after \( J_k \). If \( J_j \) is scheduled before \( J_k \), then \( J_j \) is not tardy; if \( J_j \) is scheduled after \( J_k \), then \( J_j \) is not early. Hence, we have that \( C_j^*(\lambda) \leq d_j \leq C_j^*(\lambda) \); the step size \( \Delta \) has taken us to the first point where the primitive directional derivative for increasing \( \lambda_j \) is no longer positive. If \( \lambda_j = \beta \), then the step size has been chosen as large as possible.

Suppose now \( l_j^*(\lambda) < 0 \): \( J_j \) is early in any optimal schedule for problem (L\(_A\)). Decreasing \( \lambda_j \), thereby deferring \( J_j \), is an ascent direction. We distinguish the cases \( d_j > T \), \( d_j = T \), and \( d_j < T \). Consider the case \( d_j > T \); hence, \( J_j \) is unavoidably early, and \( l_j^*(\lambda) > 0 \) for all \( \lambda \) with \( \lambda_j > 0 \). Therefore, we choose the step size as large as possible: \( \Delta = \lambda_j \). Accordingly, we also must have that \( \lambda_j^* = 0 \); otherwise, decreasing \( \lambda_j^* \) would be an ascent direction. If \( d_j = T \), then there exists an optimal schedule to problem (D) with \( \lambda_j^* = 0 \). Identify \( \mathcal{E} = \{ J_j \mid d_j \geq T \} \). We have proven the following result.

**Theorem 11.** There exists an optimal solution for the Lagrangian dual problem (D) with \( \lambda_j^* = 0 \) for each \( J_j \in \mathcal{E} \). □
Consider now the case \( d_j < T \). The procedure to compute the appropriate step size \( \Delta \) proceeds in a similar fashion as above. We identify some \( J_k \) as the first job in the schedule with \( C_k \geq d_j \). If \( J_j \) is scheduled in \( J_k \)'s position, then \( J_j \) is not early. Hence, if there were no lower bound on \( \lambda \), then decreasing \( \lambda \) would be an ascent direction up to the point where the relative weight of \( J_j \) becomes equal to the relative weight of \( J_k \). Hence, the maximum step size along this ascent direction is the largest value \( \Delta \) for which

\[
(\alpha - \beta + \lambda_j - \Delta)/p_j \geq (\alpha - \beta + \lambda_k)/p_k, \quad \text{and}
\]

\[
\lambda_j - \Delta \geq 0.
\]

Let \( \lambda_0 = (\lambda_1, \ldots, \lambda_j - \Delta, \ldots, \lambda_m) \). Suppose \( \lambda_j > 0 \). Since the relative weights for all jobs but \( J_j \) have remained the same, optimal solutions for the problems \((L_j)\) and \((L_k)\) exist with the same jobs scheduled after \( J_k \). Since \( J_j \) and \( J_k \) have now equal weights, \( J_j \) can be scheduled after \( J_k \) or before \( J_k \) in any optimal schedule for problem \((L_j)\). If \( J_j \) is scheduled after \( J_k \), then \( J_j \) is not early; if \( J_j \) is scheduled before \( J_k \), then \( J_j \) is not tardy. Hence, we find that \( C_j(\lambda) \leq d_j < C_j(\lambda) \). If \( \lambda_j = 0 \), then the step was taken as large as possible.

Termination of the ascent direction procedure occurs at some \( \lambda^* \) where all existing primitive directional derivatives are non-positive. If all primitive directional derivatives exist at such a \( \lambda^* \), we have

\[
C_j(\lambda^*) \leq d_j \leq C_j(\lambda^*), \quad \text{for } j = 1, \ldots, n.
\]

These termination conditions also apply to \( \lambda^* \), since they are necessary for optimality. They are, however, not sufficient for optimality; hence, termination may occur having \( \lambda \neq \lambda^* \), i.e., before finding the optimal vector of Lagrangian multipliers. Before implementing the ascent direction algorithm, we make use of this fact to decompose the Lagrangian dual problem \((D)\) into two subproblems. This decomposition is achieved by partitioning \( J \) into four subsets, including the sets \( T \) and \( \mathcal{E} \) we already identified.

Consider some job \( J_j \in \mathcal{F} \cap \mathcal{E} \) with \( d_j > p(J) \). If \( \lambda_j > \beta - \alpha \), then \( J_j \) will be early in any optimal solution to problem \((L_j)\). This means that \( I_j(\lambda) > 0 \), and hence we must have that \( 0 \leq \lambda_j^* \leq \beta - \alpha \). The set \( \mathcal{F} \) of jobs that share this property is determined by the following procedure.

**Partitioning Algorithm 1**

Step 0. \( \mathcal{F} \leftarrow \emptyset \), and reindex the jobs in \( \mathcal{F} \cap \mathcal{E} \) according to non-increasing due dates. Let \( k \leftarrow 1 \).

Step 1. If \( k > n - | \mathcal{E} | \) or if \( d_k < p(\mathcal{F} \cap \mathcal{E} - J_k) \), then stop. Else \( \mathcal{F} \leftarrow \mathcal{F} \cup \{ J_k \} \).

Step 2. Set \( k \leftarrow k + 1 \); go to Step 1.

Suppose some job \( J_j \in \mathcal{F} \) exists with \( d_j > T - p(\mathcal{E}) \). If we let \( \lambda_j = \beta - \alpha \), then \( C_j(\lambda) < d_j \); hence, decreasing \( \lambda \) is an ascent direction. Decreasing \( \lambda_j \) gives \((\alpha - \beta + \lambda_j)/p_j < 0 \), as a result of which the execution of \( J_j \) interferes with the execution of the jobs in \( \mathcal{E} \). We now partition the set \( \mathcal{F} \) into subsets \( \mathcal{F}_1 \) and \( \mathcal{F}_2 \) (\( \mathcal{F} = \mathcal{F}_1 \cup \mathcal{F}_2 \)) such that \( d_j \leq T - p(\mathcal{E} \cup \mathcal{F}_2) \) for each \( J_j \in \mathcal{F}_1 \), and such that \( d_j > T - p(\mathcal{E} \cup \mathcal{F}_2) \) for each \( J_j \in \mathcal{F}_2 \). To achieve this, we use the following partitioning procedure; it is similar to the first one.

**Partitioning Algorithm 2**

Step 0. Put \( \mathcal{F}_2 \leftarrow \emptyset \), let \( P \leftarrow T - p(\mathcal{E}) \), and reindex the jobs in \( \mathcal{F} \) according to non-increasing due dates. Let \( k \leftarrow 1 \).
Step 1. If \( k > |\mathcal{J}| \), then stop. If \( d_k \leq P \), then let \( \mathcal{J}_1 \leftarrow \{J_k, \ldots, J_{|\mathcal{J}|}\} \), and stop. Otherwise, \( \mathcal{J}_2 \leftarrow \mathcal{J}_2 \cup \{J_k\} \), and set \( P \leftarrow P - p_k \).

Step 2. Set \( k \leftarrow k + 1 \); go to Step 1.

Let \( \mathcal{R} = \mathcal{T} - \mathcal{E} - \mathcal{J} \).

**Theorem 12.** For each \( J_j \in \mathcal{J}_1 \), we have that \( \lambda_j^* = \beta - \alpha \).

**Proof.** Since we have \( p (\mathcal{T} \cup \mathcal{R}) \leq d_j \leq T - p (\mathcal{E} \cup \mathcal{J}_2) \), the result follows. \( \square \)

At this stage, we can decompose the Lagrangian dual problem (D) into two subproblems. Since \((\alpha - \beta + \lambda_j^*)/p_j = 0\) for each \( J_j \in \mathcal{J}_1 \), the jobs in \( \mathcal{J}_1 \) do not interfere with the execution of the other jobs. However, \( \mathcal{T} \) and \( \mathcal{R} \) interfere with each other, and \( \mathcal{E} \) and \( \mathcal{F}_2 \) interfere with each other. On the one hand, we have the dual problem restricted to the sets \( \mathcal{T} \) and \( \mathcal{R} \); on the other hand, we have the dual problem restricted to the sets \( \mathcal{F}_2 \) and \( \mathcal{E} \). In each optimal schedule for problem (D), the jobs in \( \mathcal{T} \) and \( \mathcal{R} \) are scheduled in the interval \([0, p (\mathcal{T} \cup \mathcal{R})]\), and the jobs in \( \mathcal{E} \) and \( \mathcal{F}_2 \) are scheduled in the interval \([T - p (\mathcal{E} \cup \mathcal{F}_2), T]\). We give step-wise descriptions of the ascent direction algorithms for these two subproblems. Both are based upon the primitive directional derivatives and the step sizes we discussed earlier. The jobs in \( \mathcal{J}_1 \) are scheduled somewhere in the interval \([p (\mathcal{T} \cup \mathcal{R}), T - p (\mathcal{E} \cup \mathcal{F}_2)]\); they are left out of consideration. We introduce some new notation. Let \( (L_\mathcal{T} \cup \mathcal{J}_1 (\lambda)) \) and \( (L_\mathcal{E} \cup \mathcal{F}_2 (\lambda)) \) denote the Lagrangian problem restricted to the set \( \mathcal{R} \cup \mathcal{T} \) and to the set \( \mathcal{E} \cup \mathcal{F}_2 \); let \( L_\mathcal{R} \cup \mathcal{T} (\lambda) \) and \( L_\mathcal{E} \cup \mathcal{F}_2 (\lambda) \) denote their optimal solution values.

**Ascent Direction Algorithm for the Set \( \mathcal{T} \cup \mathcal{R} \)**

Step 0. For each \( J_j \in \mathcal{T} \), set \( \lambda_j \leftarrow \lambda_j^* = \beta \); for each \( J_j \in \mathcal{R} \), set \( \lambda_j \leftarrow \beta \). Solve \((L_\mathcal{T} \cup \mathcal{J}_1 (\lambda))\), settling ties arbitrarily; compute the job completion times.

Step 1. For each \( J_j \in \mathcal{R} \), do the following:

(a) If \( C_j (\lambda) < d_j \), identify \( J_k \) as the first job in the schedule with \( C_k \geq d_j \). Compute the largest value \( \Delta \) such that

\[
(\alpha - \beta + \lambda_j + \Delta)/p_j \geq (\alpha - \beta + \lambda_k)/p_k, \quad \text{and} \quad \lambda_j + \Delta \geq \beta - \alpha.
\]

(b) If \( C_j (\lambda) > d_j \), identify \( J_k \) that is the first job in the schedule with \( C_k - p_k + p_j \leq d_j \). Compute the largest value \( \Delta \) such that

\[
(\alpha - \beta + \lambda_j + \Delta)/p_j = (\alpha - \beta + \lambda_k)/p_k, \quad \text{and} \quad \lambda_j + \Delta \leq \beta.
\]

Increase \( \lambda_j \) by \( \Delta \), reposition \( J_j \) according to its new relative weight, and update the job completion times.

Step 2. If no multiplier adjustment has taken place, then compute \( L_\mathcal{E} \cup \mathcal{F}_2 (\lambda) \) and stop. Otherwise, go to Step 1.
Theorem 13. The procedure described above generates a series of monotonically increasing values $L_{\mathcal{R} \cup \mathcal{T}}(\lambda)$.

Proof. First, consider some $J_j \in \mathcal{R}$ with $C_j(\lambda) < d_j$; decreasing $\lambda_j$ is an ascent direction. For brevity, we let $\mu_j = \alpha - \beta + \lambda_j$ for each $j$ ($j = 1, \ldots, |\mathcal{R} \cup \mathcal{T}|$). We reindex the jobs in order of non-increasing values $\mu_j/p_j$, settling all ties arbitrarily except for $J_j$: we give $J_j$ the largest index possible. Accordingly, we obtain the sequence $(J_1, \ldots, J_{|\mathcal{R} \cup \mathcal{T}|})$, which is optimal for problem $(L_{\mathcal{R} \cup \mathcal{T}})$, with job completion times $C_1, \ldots, C_{|\mathcal{R} \cup \mathcal{T}|}$. We note that $C_j = C_j(\lambda)$. Let $\Lambda$ be the step size computed as prescribed in the ascent direction algorithm, and let $\bar{\lambda} = (\lambda_1, \ldots, \lambda_j - \Delta_1, \ldots, \lambda_{|\mathcal{R} \cup \mathcal{T}|})$.

We distinguish the case that condition (11) holds with equality from the case that condition (12) holds with equality. Consider the first case; accordingly let $J_k$ be the job specified in the ascent direction procedure. In more detail, the sequence under consideration is $(J_1, \ldots, J_{j-1}, J_j, J_{j+1}, \ldots, J_k, J_{k+1}, \ldots, J_{|\mathcal{R} \cup \mathcal{T}|})$; an optimal sequence for problem $(L_{\mathcal{R} \cup \mathcal{T} \bar{\lambda}})$ is then $(J_1, \ldots, J_{j-1}, J_j, J_{j+1}, \ldots, J_k, J_{k+1}, \ldots, J_{|\mathcal{R} \cup \mathcal{T}|})$. The job completion times for the latter sequence can conveniently be expressed in terms of $C_1, \ldots, C_{|\mathcal{R} \cup \mathcal{T}|}$. We now prove that $L_{\mathcal{R} \cup \mathcal{T} \bar{\lambda}} > L_{\mathcal{R} \cup \mathcal{T}}(\lambda)$. We have

\[
L_{\mathcal{R} \cup \mathcal{T} \bar{\lambda}} = \sum_{i=1}^{j-1} \mu_i C_i + (\mu_j - \Delta)(C_j(\lambda) + \sum_{i=j+1}^{k} p_i) + \sum_{i=j+1}^{k} \mu_i(C_i - p_i) + \sum_{i=k+1}^{|\mathcal{R} \cup \mathcal{T}|} \mu_i C_i + \sum_{i=1}^{|\mathcal{R} \cup \mathcal{T}|} (\beta - \lambda_i) d_i + \Delta d_j
\]

\[
= L_{\mathcal{R} \cup \mathcal{T}}(\lambda) - p_j \sum_{i=j+1}^{k} \mu_i + \mu_j \sum_{i=j+1}^{k} p_i - \Delta(C_j(\lambda) + \sum_{i=j+1}^{k-1} p_i - d_j)
\]

\[
= L(\lambda) - p_j \sum_{i=j+1}^{k-1} \mu_i + \mu_j \sum_{i=j+1}^{k-1} p_i - \Delta(C_j(\lambda) + \sum_{i=j+1}^{k-1} p_i - d_j) + (\mu_j - \Delta)p_k - p_j \mu_k.
\]

Note that $(\mu_j - \Delta)/p_j = \mu_k/p_k$; hence, we have $(\mu_j - \Delta)p_k - p_j \mu_k = 0$. This implies that

\[
L(\bar{\lambda}) \geq L(\lambda) + p_j \sum_{i=j+1}^{k-1} \left(p_i(\mu_j/p_j - \mu_i/p_i) - \Delta(C_j(\lambda) + \sum_{i=j+1}^{k-1} p_i - d_j)ight).
\]

Since $d_j > C_j(\lambda) + \sum_{i=j+1}^{k-1} p_i$, $\mu_j/p_j > \mu_i/p_i$ for each $i$ ($i = j+1, \ldots, k-1$), and $\Delta > 0$, we have that $L_{\mathcal{R} \cup \mathcal{T} \bar{\lambda}} > L_{\mathcal{R} \cup \mathcal{T}}(\lambda)$.

Now assume that the condition (12) holds with equality and the condition (11) does not: $\Delta = \alpha - \beta + \lambda_j$. This implies that $J_j$ will now be placed after some job $J_h$, with $j < h < k$. For this case, the second sequence is $(J_1, \ldots, J_{j-1}, J_{j+1}, \ldots, J_h, J_j, J_{k+1}, \ldots, J_k, \ldots, J_{|\mathcal{R} \cup \mathcal{T}|})$. We perform a similar analysis as above to obtain

\[
L_{\mathcal{R} \cup \mathcal{T} \bar{\lambda}} = L_{\mathcal{R} \cup \mathcal{T}}(\lambda) - p_j \sum_{i=j+1}^{h} \mu_i + \mu_j \sum_{i=j+1}^{h} p_i - \Delta(C_j(\lambda) + \sum_{i=j+1}^{h} p_i - d_j)
\]
At this point, similar arguments as before apply to show that \( L^{R \cup T}(\lambda) > L^{R \cup T}(\lambda) \).

Second, consider the case that \( C_j^+(\lambda) > d_j \) for some \( J \in \mathcal{R} \); increasing \( \lambda_j \) is an ascent direction. Let \( \Delta \) be the desired step size, computed as described in the ascent direction algorithm. The proof to show that \( L^{R \cup T}(\lambda_1, \ldots, \lambda_J + \Delta, \ldots, \lambda_{|R \cup T|}) > L^{R \cup T}(\lambda_1, \ldots, \lambda_j, \ldots, \lambda_{|R \cup T|}) \) follows the same lines as above. \( \square \)

Ascent Direction Algorithm for the Set \( J_2 \cup \mathcal{E} \)

Step 0. Set \( \lambda_j \leftarrow \beta - \alpha \) for each \( J \in \mathcal{F}_2 \), and \( \lambda_j \leftarrow \lambda_j^* = 0 \) for each \( J \in \mathcal{E} \). Solve \((L^{R \cup T}_\lambda, J_2)\), settling ties arbitrarily; compute the job completion times.

Step 1. For each \( J \in \mathcal{F}_2 \), do the following:

(a) If \( C_j^+(\lambda) < d_j \), identify \( J_k \) as the first job in the schedule with \( C_k \geq d_j \). Compute the largest value \( \Delta \) such that

\[
(\alpha - \beta + \lambda_j - \Delta)/p_j \geq (\alpha - \beta + \lambda_k)/p_k, \quad \text{and} \quad \Delta \leq \lambda_j.
\]

Decrease \( \lambda_j \) by \( \Delta \), reposition \( J_j \) according to its new relative weight, and update the job completion times.

(b) If \( C_j^+(\lambda) > d_j \), identify \( J_k \) that is the first job in the schedule with \( C_k \leq d_j + p_k - p_j \). Compute the largest value for \( \Delta \) such that

\[
(\alpha - \beta + \lambda_j + \Delta)/p_j = (\alpha - \beta + \lambda_k)/p_k, \quad \text{and} \quad \lambda_j + \Delta \leq \beta - \alpha.
\]

Increase \( \lambda_j \) by \( \Delta \), reposition \( J_j \) according to its new relative weight, and update the job completion times.

Step 2. If no multiplier adjustment has taken place, then compute \( L^{R \cup T}(\lambda) \) and stop. Otherwise, go to Step 1.

**Theorem 14.** The procedure described above generates a series of monotonically increasing values \( L^{R \cup T}(\lambda) \).

**Proof.** The proof proceeds along the same lines as the proof of Theorem 13. \( \square \)

For each \( J \in \mathcal{F}_1 \), let \( C_j \) and \( \lambda_j \) denote the completion time and the Lagrangian multiplier upon termination of the appropriate ascent direction algorithm. We note that \( \lambda_j = \beta \) for each \( J \in \mathcal{F}_1 \), \( \lambda_j = \beta - \alpha \) for each \( J \in \mathcal{T} \), and \( \lambda_j = 0 \) for each \( J \in \mathcal{E} \). Hence, the overall Lagrangian lower bound is given by

\[
L(\lambda) = \sum_{J \in \mathcal{T}} \alpha C_j + \sum_{J \in \mathcal{F}_1} \alpha d_j + \sum_{J \in \mathcal{E}} [(\alpha - \beta) C_j + \beta d_j] + \sum_{J \in R \cup T} [(\alpha - \beta + \lambda_j) C_j - (\beta - \lambda_j) d_j].
\]
5. Computational results

The algorithm was coded in the computer language C; the experiments were conducted on a Compaq-386/20 Personal Computer. The algorithm was tested on instances with 8, 10, 12, 15, and 25 jobs. The processing times were generated from the uniform distribution [10,100]. The due dates were generated from the uniform distribution \( [P(1-T-R/2), P(1-T+R/2)] \), where \( P = \sum_{j=1}^{n} p_j \) and where \( R \) and \( T \) are parameters. For both parameters, we considered the values 0.2, 0.4, 0.6, 0.8, and 1.0. This procedure to generate due dates parallels the procedure described by Potts and Van Wassenhove (1985) for the weighted tardiness problem. For each combination of \( T, P, \) and \( n \), we generated 5 instances. Each instance was considered with \( \alpha=1 \) and with \( \beta \) running from 2 to 5.

The general impression was that instances become difficult with smaller values of \( T \), with smaller values of \( R \), and with smaller values of \( \beta \). A small value of \( T \) induces relative large due dates, implying that the machine will be idle for some time before processing the first job. A small value of \( R \) induces due dates that are close to each other; it is then harder to partition the jobs. A large value of \( \beta \) implies that earliness is severely penalized; most jobs will therefore be tardy. Accordingly, the instances with \( T=0.2, R=0.2, \) and \( \beta=5 \) are the hardest; the instances with \( T=1.0, R=1.0, \) and \( \beta=2 \) are the easiest.

Table 2 exhibits a summary of our computational results; we only report the results for the instances with \( T \) and \( R \) equal. It shows that instances with up to 10 jobs are easy. For \( n=12 \), the instances with \( T=R=0.2 \) require already considerable effort. For \( n=20 \), only the choice \( T=R=1.0 \) induces instances that are solvable within reasonable time limits. It is likely, however, that the performance of the algorithm is considerably enhanced by fine-tuning the algorithm to specific instances. Currently, all lower bounds are computed in each node of the tree; Lagrangian relaxation, for instance, is useless for instances with \( T=R=0.2 \).

6. Conclusions

Although machine idle time is a practical instrument to reduce inventory cost, a considerable lack of theoretical analysis of related machine scheduling problems exists. Within this context, we have addressed the \( 1 | \alpha \sum C_j + \beta \sum E_j | \) problem for the case that \( \alpha < \beta \). It is a very difficult problem from a practical point of view.

Acknowledgement

The authors like to thank Jan Karel Lenstra for his helpful comments.

Table 2. Computational results. For each combination of $n$ ($n=8, 10, 12, 15, 20$), of $T$ and $R$ ($T=R=0.2, 0.4, 0.6, 0.8, 1.0$), and of $\beta$ ($\beta=2, 3, 4, 5$), we present the average number of nodes and the average number of seconds; the average was computed over 5 instances. All averages were rounded up to the nearest integer. The sign '-' indicates that not all instances of this particular combination could be solved without examining more than 100,000 nodes.
