We show that the atom-molecule mixture formed in a degenerate atomic Fermi gas with interspecies repulsion near a Feshbach resonance constitutes a peculiar system where the atomic component is almost nondegenerate but quantum degeneracy of molecules is important. We develop a thermodynamic approach for studying this mixture, explain experimental observations, and predict optimal conditions for achieving molecular Bose-Einstein condensation.

DOI: 10.1103/PhysRevA.69.031602 PACS number(s): 03.75.Ss, 05.30.Jp, 05.20.Dd, 32.80.Pj

Interactions between particles play a crucial role in the behavior of degenerate quantum gases. For instance, the sign of the effective mean-field interaction determines the stability of a large Bose-Einstein condensate (BEC), and the shape of such a condensate in a trap can be significantly altered from its ideal-gas form [1]. In degenerate Fermi gases the effects of mean-field interactions are usually less pronounced in the size and shape of the trapped cloud, and these quantities are mostly determined by Fermi statistics. The strength of the interactions, however, can be strongly increased by making use of a Feshbach resonance [2,3], and then the situation changes.

Recent experiments present two types of measurement of the interaction energy in a degenerate two-component Fermi gas near a Feshbach resonance [4–7]. At JILA [5] and at MIT [7] the mean-field energy was found from the frequency shift of a rf transition for one of the atomic states. The results are consistent with the magnetic-field dependence of the scattering length a, the energy being positive for a > 0 and negative for a < 0. In the Duke [4] and ENS [6] experiments with 6Li, the results are quite different. The interaction energy was obtained from the measurement of the size of an expanding cloud released from the trap. A constant ratio of the interaction to Fermi energy, $E_{\text{int}}/E_F \approx -0.3$, was found around resonance, irrespective of the sign of a [4,6]. It was explained in Ref. [4] by claiming a universal behavior in this strongly interacting regime [8]. The ENS studies in a wide range of magnetic fields [6] found that $E_{\text{int}}$ changes to a large positive value when a is tuned positive, but only at a field strongly shifted from resonance.

In contrast to the JILA [5] and MIT [7] studies providing a direct measurement of the mean-field interaction energy, the Duke [4] and ENS [6] experiments measure the influence of the interactions on the gas pressure. An interpretation of the ENS experiment involves the creation of weakly bound molecules via three-body recombination at a positive a [6]. Far from resonance, the binding energy of the produced molecules and, hence, their kinetic energy are larger than the trap depth and the molecules escape from the trap. The interaction energy is then determined by the repulsive interaction between atoms and is positive [6]. Close to resonance, the three-body recombination is efficient [9] and the molecules remain trapped as their binding energy $\epsilon_B$ is smaller than the trap depth [6,9]. They come to equilibrium with the atoms, reducing the pressure in the system.

Away from resonances, the interaction strength is proportional to a, and is given by $g = 4\pi\hbar^2a/M$, with M the atom mass. Close to resonance this relation is not valid, as the value of |a| diverges to infinity and the scattering process strongly depends on the collision energy. For Boltzmann gases, already in the 1930s, Beth and Uhlenbeck [10] calculated the second virial coefficient by including both the scattering and bound states for the relative motion of pairs of atoms [11]. A small interaction-induced change of the pressure in this approach is negative on both sides of the resonance [12,13].

However, current experiments are not in the Boltzmann regime. In this paper we show that the atom-molecule mixture formed in a cold atomic Fermi gas constitutes a peculiar system in which the atomic component is almost nondegenerate, whereas quantum degeneracy of the molecules can be very important. This behavior originates from a decrease of the atomic fraction with temperature. It is present even if the initial Fermi gas is strongly degenerate in which case almost all atoms are converted into molecules. We develop a thermodynamic approach for studying this mixture, predict optimal conditions for achieving molecular BEC, and properly describe the interaction effects as observed at ENS [6].

We assume that fermionic atoms are in equilibrium with weakly bound (bosonic) molecules formed in the recombination process. The molecules are treated as point bosons. Atom-molecule and molecule-molecule interactions are omitted at first, and will be discussed in a later stage. For a large scattering length $a > 0$, the binding energy of the weakly bound molecules is $\epsilon_B = \hbar^2/(Ma^6)$, and their size is roughly given by $a/2$. For treating them as point bosons, this size should be smaller than the mean interparticle separation. This requires the inequality $n(a/2)^3 < 1$, which at densities...
where \( n = 10^{13} \text{ cm}^{-3} \) is satisfied for \( a < 18 \text{ 000} \mu \text{Bohr} \), and excludes a narrow vicinity of the Feshbach resonance.

The presence of molecules reduces the number of particles in the atomic component and to an essential extent lifts its quantum degeneracy. The molecular chemical potential is negative in the absence of atom-molecule and molecule-molecule mean field, and thermal equilibrium between atoms and molecules requires a negative chemical potential for the atoms. We thus assume a priori that the occupation numbers of the states of atoms are small. This proves to be the case at any temperature, except for very low \( T \) where the atomic fraction is negligible. Under these conditions we omit pairing correlations between the atoms, which are important for describing a crossover from the BCS to BEC regime \([14–17]\) and can be expected even in the nonsuperfluid state.

Assuming equal densities of the atomic components, labeled as \([\uparrow] \) and \([\downarrow] \), their chemical potentials are \( \mu_\uparrow = \mu_\downarrow = \mu \), where \( \mu \) is the chemical potential of the system as a whole. The molecular chemical potential is \( \mu_m = -\epsilon_B + \tilde{\mu}_m \), with \( \tilde{\mu}_m \approx 0 \) being the chemical potential of an ideal gas of bosons with the mass \( M \). The condition of thermal equilibrium \( \mu_\uparrow + \mu_\downarrow = \mu_m \) then reads

\[
2\mu = -\epsilon_B + \tilde{\mu}_m.
\]

From Eq. (1) we will obtain the number of molecules \( N_m \) and the number of atoms \( N_a \) for given temperature \( T \) and total number of atomic particles \( N = N_a + 2N_m \). This requires us to obtain the expression for the occupation numbers of the atoms and the dependence of \( \mu \) on \( N_a \).

The main difficulty with constructing a thermodynamic approach for the degenerate molecule-atom mixture is related to the resonance momentum-dependent character of the atom-atom interactions. This difficulty is circumvented for small occupation numbers of the atoms. Then, even at resonance, the interaction energy is equal to the mean value of the interaction potential for a given relative momentum of a colliding pair, averaged over the momentum distribution. In this respect, the interaction problem becomes similar to the calculation of the total energy of a heavy impurity as caused by its interactions with the surrounding electrons in a metal \([19]\). This approach leads to a relation between the collision-induced shift of the energy levels of particles in a large spherical box, and the scattering phase shift. Adding the integration over the states of the center-of-mass motion for pairs of atoms, we find that the total energy of interatomic interaction is equal to

\[
\sum_{k,k'} g_{kk'} v(k,\mu,T)v(k',\mu,T)/V,
\]

where \( v_1 \) and \( v_2 \) are occupation numbers of single-particle momentum states, and \( V \) is the volume (cf. Ref. \([19]\)). The momentum-dependent coupling constant is given by

\[
g_{kk'} = -\frac{4\pi\hbar^2}{M} \frac{\delta(|\mathbf{k} - \mathbf{k}'|/2)}{|k - k'|/2}.
\]

The phase shift \( \delta \) is expressed through the relative momentum \( q = |\mathbf{k} - \mathbf{k}'|/2 \) and the scattering length \( a \) as \( \delta = -\text{arctan}(qa) \). In the limit of \( q|a| \ll 1 \), Eq. (2) transforms into the ordinary coupling constant \( g = 4\pi\hbar^2a/M \).

As we have \( v(k,\mu,T) = v_1(k,\mu,T) = v_2 \), the total energy of the atomic component and the number of particles in this component can be written in the form

\[
E_a = \sum_k \frac{\hbar^2 k^2}{M} v_1 + \sum_{k,k'} \frac{g_{kk'}}{V} v_1 v_1, \quad N_a = 2 \sum_k v_1.
\]

In our mean-field approach, the entropy of the atoms is given by the usual combinatorial expression \([18]\)

\[
S_a = -2 \sum_k [v_1 \ln(v_1 + 1 - v_1)ln(1 - v_1)].
\]

Equations (3) and (4) immediately lead to an expression for the atomic grand potential \( \Omega_a = E_a - TS_a - \mu N_a \). Then, using the relation \( \mu_a = -\partial \Omega_a/\partial N_a \), we obtain for the occupation numbers of atoms

\[
v_1 = \left[\exp((\epsilon_1 - \mu)/T) + 1\right]^{-1},
\]

where \( \epsilon_1 = \hbar^2 k^2/2M + U_1 \), and \( U_1 = \sum_k g_{kk'} v_1 v_1/V \) is the mean field acting on the atom with momentum \( \mathbf{k} \). Accordingly, the expression for the grand potential and pressure of the atomic component reads

\[
\Omega_a = -P_a V = \sum_k [2T \ln(1 - v_1) - U_1 v_1].
\]

This set of equations is completed by the relation between the density of bosonic molecules and their chemical potential. In the absence of molecular BEC we have

\[
n_m = (\sqrt{2}/\Lambda_f)\sqrt{\frac{2}{\gamma}} \left[ \exp(\mu_{ad}/T) \right],
\]

where \( g_\sigma(x) = \sum_{j=1}^n x^j/j^n \), and \( \Lambda_f = (2\pi\hbar^2/MT)^{1/2} \) is the thermal de Broglie wavelength for the atoms. For \( n_m \Lambda_f^3 > 7.38 \), the molecular fraction becomes Bose condensed, and we have \( \mu = -\epsilon_B/2 \). Similarly, the energy, entropy, and grand potential of the molecules are given by usual equations for an ideal Bose gas \([11]\).

From Eqs. (1)–(7) we obtain the fraction of unbound atoms \( n_{ad}/n \) and the fraction of atoms bound into molecules, \( 2n_{ad}/n \), as universal functions of two parameters: \( T/\epsilon_B \) and \( n\Lambda_f^3 \), where \( n \) is the total density of atomic particles. The dependence of atomic and molecular fractions on \( T/\epsilon_B \) for two values of \( n\Lambda_f^3 \) is shown in Fig. 1. The molecular fraction increases and the atomic fraction decreases with decreasing \( T/\epsilon_B \). Occupation numbers of the atoms are always small, whereas quantum degeneracy of molecules is important. The dotted line in Fig. 1(b) indicates the onset of molecular BEC.

This mixture was realized in the ENS experiment \([6]\), where the occupation numbers for the molecules were up to 0.3 and the molecular fraction was exceeding the atomic one. In the recent studies \([20–23]\) almost all atoms were converted into molecules by sweeping the magnetic field across the resonance, and at ENS \([20]\) the temperature was within a factor of 2 from molecular BEC. Remarkably, one can modify the molecular fraction and degeneracy parameter \( n_m \Lambda_f^3 \) by adiabatically tuning the atom-atom scattering length, as shown in Fig. 2. The decrease of \( a \) increases the binding energy \( \epsilon_B \) and the molecular fraction, and thus
For the atoms this shift is in a gas are readily included in our approach for most constant and then decreases due to heating.

The atom-molecule and molecule-molecule interactions are optimal for values of our results. From Fig. 2 one then concludes that the conditions for achieving molecular BEC are not significantly modify our results. From Fig. 2 one then concludes that the conditions for achieving molecular BEC are optimal for values of with the molecular distribution function $\rho_{mn}$. However, as the time $t=\hbar/\epsilon_B$, they cannot adiabatically follow to a deeper bound state and dissociate into atoms which acquire kinetic energy. Thus the system expands symmetrically as an ideal gas of $N$ atoms, with the initial density profile. The momentum distribution $f_{\mathbf{k}}$ will be a sum of the initial atomic momentum distribution and one that arises from the dissociated molecules. The latter is found assuming an abrupt change of $a$ and, hence, projecting the molecular wave function on a complete set of plane waves. This gives rise to a distribution $c(q)$ for the relative momentum $q$. The single-particle momentum distribution for the atoms produced out of molecules results then from convoluting $c(|\mathbf{k}|-|\mathbf{k}'|/2)$ with the molecular distribution function $n_m(\mathbf{k}+\mathbf{k}')$ by integrating over $\mathbf{k}'$. One can establish a relation between the expansion velocity $v_0$ of this nonequilibrium system and the expansion velocity $c_0$ of an ideal equilibrium two-component atomic Fermi gas which has the same density and temperature: $4\pi n_{\text{HEV}}^n \frac{\hbar}{f_{\mathbf{k}}}$

FIG. 1. Fraction of unbound atoms $n_a/n$ (lower curves, bold) and fraction of atoms bound into molecules, $2n_m/n$ (upper curves) vs $T/\epsilon_B$: (a) $n\Lambda_T^3=2.5$, squares and circles show the ENS data [20]; (b) $n\Lambda_T^3=14.8$, and the vertical lines indicate the onset of molecular BEC. Dashed curves are obtained including atom-molecule and molecule-molecule interactions.
\( \int_{0}^{\infty} dk \frac{k^2 \tilde{n}_k}{2} \), with \( \tilde{n}_k \) being the ideal-gas momentum distribution. Using the scaling approach [24,25], one can find that in the spherical case the velocity \( c_0 \) coincides with the expansion velocity of the hydrodynamic Fermi gas in the absence of mean-field interactions and, accordingly, is given by \( c_0^2 = 5p_0/3p \), where \( p_0 = 2E_0/3V \) is the pressure.

The relative difference between the squared size of the expanding cloud in the two described cases can be treated as the ratio of the interaction to kinetic energy and called the interaction shift. This interaction shift is then given by the relative difference between the two squared velocities: \( \beta = (c_2^2 - v_0^2)/v_0^2 \). Our results for this quantity are calculated for experimental conditions and are presented in Fig. 3. The sound velocity \( c_s \) was obtained using the above developed approach including only atom-atom interactions. The field region where \( n(a/2)^3 > 1 \) is beyond the validity of this approach and is shown by the dashed curve. In Fig. 3 we also show our previous results for fields \( B > 810 \) G \( (a < 0) \) and \( B < 700 \) G \( (0 < a < 2000a_0) \), where molecules are absent [6].

Our quantum-statistical approach gives a negative interaction shift on both sides of the Feshbach resonance, in good quantitative agreement with the experiment. Without molecules present, the interaction energy would jump to positive values left from resonance, as can be seen from our calculation in Ref. [6]. This demonstrates that the apparent field shift from resonance, where a sign change in the interaction energy is observed, is an indirect signature of the presence of molecules in the trap.

For high temperatures \( T \gg E_F \) and small binding energy \( \varepsilon = T \), we find that \( \beta \) has a universal behavior and is proportional to the second virial coefficient. However, this only holds at high temperatures (cf. Ref. [13]), and at low \( T \) the molecule-molecule interaction can strongly influence the result. For \( T \) approaching the temperature of molecular BEC, which is \( T_c = \hbar^2 n^{3/2}/M = 0.2 \) \( E_F \), the atomic fraction is already small and the sound velocity \( c_s \) is determined by the molecular cloud. For \( a \ll \Lambda_T \) we find \( c_s^2 = 0.4 T_c/M + n_{gm}/2M \), where the second term is provided by the molecule-molecule interaction and is omitted in the high-\( T \) approach. The ratio of this term to the first one is \( -5(na^3)^{1/3} \). For \( B = 700 \) G at densities of Ref. [6], it is equal to 1 and is expected to grow when approaching the resonance.

Thus, except for a narrow region where \( n|a|^3 \gg 1 \), one cannot speak of a universal behavior of the shift \( \beta \) on both sides of the resonance. The situation depends on possibilities of creating an equilibrium atom-molecule mixture. Moreover, at low temperatures the universality can be broken by the molecule-molecule interactions.
