The Effect of Vancomycin and Tobramycin on the Tensile Properties of Cured Low Viscosity Bone Cements

JEAN-NOEL ARGENSEN, MD,1 NICO VERDONSCHOT, PhD,2 PHILIPPE SEYRAL, MD,3 and RICK HUISKES, PhD2

From the 1Department of Orthopaedic Surgery, Aix-Marseille University, Hospital Sainte-Marguerite, Marseille, France, 2Institute of Biomechanics, Nijmegen University, Nijmegen, The Netherlands, and 3Department of Microbiology, Aix-Marseille University, Hospital La Timone, Marseille, France

INTRODUCTION

Infection remains the most serious short-term complication following total joint arthroplasty. Methods of reducing its frequency include meticulous surgical technique, improved surgical environment using laminar flow, and the use of prophylactic systemic antibiotics.

Antibiotics may also be added to the bone cement and have been proposed either for prophylaxis or treatment of infections in orthopaedic surgery (1). Gentamicin has been the most commonly used antibiotic, but resistance to this compound has increased in recent years and major bacterial pathogens involved in infected arthroplasties, such as staphylococci and pseudomonas, are now frequently resistant to gentamycin.

The purpose of this study was to investigate whether the tensile mechanical properties of four low viscosity bone cements are affected when admixed with vancomycin and tobramycin. We chose these antibiotics because vancomycin is effective against nearly all staphylococci and tobramycin is effective against pseudomonas.

MATERIALS AND METHODS

Four low-viscosity cements were used throughout the study: CMW3 (CMW, Exeter, U.K.), LVC (Zimmer, Warsaw, Indiana, USA), Palacos BV (Schering-Plough, Levallois, France), and Sulfix 60 (Allopro-Sulzer, Winterthur, Switzerland). For each cement, four tests were conducted: without antibiotics, with 2 g of vancomycin and 1 g of tobramycin, with 4 g of vancomycin and 2 g of tobramycin, and with 2 g of vancomycin alone. The antibiotic powder was added to the polymer powder and mixed thoroughly by hand. The powder and the monomer were then mixed according to the manufacturer’s instructions for 2 min at a rate of about 100 cycles per min. For each test several specimens were studied (Table 1).

The mould that was used for the production of the bone cement specimens for the tension tests consisted of an aluminium box with a lid. It was covered on the inside by a 1 cm polytetrafluoroethylene (PFTE) layer. The cement filling space in the box was 5 × 46 × 200 mm. In the four corners of the box, there were holes to allow excess cement to escape when the box was closed. After curing under pressure (by applying a load of approximately 5 kg) for 18 min at 24°C, a 5 mm thick bone cement plate could be obtained from the mould.

After moulding, the specimens were machined according to DIN 53-455 on a Bridgeport CNC mill to a dumbbell shape. X-rays were taken of each specimen, so that the internal void distribution could be visualized and large deficiencies in mechanical properties be interpreted. Specimens with voids in the radius that would obviously lead to failure were discarded. The

Fig. 1. The shape and dimensions of the tensile test specimens, in mm.

specimens, 20 cm in total length, had a gauge length of 5 cm (Fig. 1). The width (mm) and thickness (mm) of three cross-sections along the gauge length of each specimen were checked with a micrometer around 10 mm and 5 mm, respectively. Mean values were used and the cross-sectional area was calculated, in mm².

After machining, all the specimens were stored at 21°C under a relative humidity of 20% for a minimum of 6 weeks. For tensile testing the specimens were fixed in an Instron testing machine (model TT-CM) by two clamps 10 cm apart. A 5 cm displacement gauge was fixed to the gauge length. The tension tests were performed at a crosshead speed of 25 mm/min. The data were collected by a computer and elastic modulus (MPa), tensile strength (MPa) and fracture strain were determined. A total of 78 specimens were tested. Each specimen came from a single mix of cement. Statistical analysis using the Student's t-test was used to compare the means of the tensile strength and fracture strain of the groups with and without antibiotic.

RESULTS
A total of 76 specimens were effectively tested, two of the 78 specimens led to mechanical failure, which was due to the presence of large air voids (>14 mm in radius) in the region of the measuring area. For all the other specimens (showing voids of <1 mm in radius) the tension test could be conducted routinely.

Figs. 2–4 show the resulting Young’s moduli, tensile strengths and fracture strains for the four low viscosity bone cements, with normal cement (P), after addition of single dose (SD) or double dose (DD) of antibiotic (vancomycin + tobramycin) or with vancomycin (Va) alone.

Effect of antibiotic addition
The addition of 2 g of vancomycin did not significantly affect the tensile mechanical properties of the four cements.

The addition of 2 g of vancomycin and 1 g of tobramycin significantly decreased the elastic modulus by 5 to 10%, except for Palacos, which was not affected. The addition of 2 g of vancomycin and 1 g of tobramycin always decreased the tensile strengths of the cements, but the difference was only significant for Sulfix (p = 0.001).

The addition of 2 g of vancomycin and 1 g of tobramycin did not significantly affect the fracture strain, except for Sulfix (p = 0.003).

The addition of a double dose of antibiotic (vancomycin 4 g + tobramycin 2 g) did not significantly change the results obtained with a single dose.

Tensile properties of the four low viscosity cements
The tensile strength and fracture strain of Palacos BV and Sulfix 60 were significantly higher than those of CMW3 and Zimmer LVC, without any antibiotic (p < 0.001; Student's t test).

After antibiotic addition, Palacos BV and Sulfix 60 always showed higher tensile strength and fracture strain, but this was not significant in all cases.

After antibiotic addition Palacos BV always had a significantly higher tensile strength than the three other cements.

DISCUSSION
The addition of an antibiotic in polymethylmethacrylate (PMMA) has proved to be efficient in reducing
infection after arthroplasty (2) and has been successfully used in the treatment of infected arthroplasty, where the involved micro-organism is sensitive to the antibiotic admixed in the cement (3). The most common bacterial pathogen involved in joint replacement infection is staphylococcus coagulase positive or negative, which is almost uniformly sensitive to vancomycin. Tobramycin is effective against Gram negative micro-organisms. The elution of these two antibiotics from PMMA has recently been studied in vitro (4), and the antibiotics were found in useful concentrations in the surrounding tissues. In another work (5), measurable concentrations were found after 8 months, with no alteration of the antimicrobial
activity caused by polymerization and no evidence of micro-organism growth after 50 days for vancomycin and 60 days for tobramycin.

The purpose of this study was to investigate the effect on the tensile properties of the cement after addition of antibiotics. Lautenschlager et al. (6, 7) showed the absence of deleterious effects of gentamycin powder of up to 5 g on the tensile properties. Our results with vancomycin confirm the absence of any significant effect on the tensile properties of the four low viscosity cements studied. Simultaneous addition of vancomycin and tobramycin only affects the tensile properties of Sulfix, while the tensile strength and fracture strain remain much higher than for CMW3 and Zimmer LVC.

The tensile strength was 24 to 43 MPa for vancomycin-loaded PMMA for the four low viscosity cements, compared with 18 MPa with conventional viscosity cement loaded with vancomycin, as reported by Lawson et al. (4) for a small number of specimens. These results also compare favourably with previous reports of diametral tensile strength obtained with gentamycin (8). The better mechanical characteristics after antibiotic admixing obtained with low viscosity cements have already been reported in the literature (9).

However, air voids due to poor techniques in the powder mixing can lead to early fractures (10), as was the case for two of our 78 specimens (Fig. 5). New technologies for cement preparation, or industrial powder preparation including antibiotics effective against the common pathogens, may decrease the porosity of the cement.

Whereas tobramycin has frequently been studied and incorporated in bone cement, very little work has been reported on vancomycin loaded PMMA. This antibiotic appears to fulfil the criteria proposed by Murray (11) for heat stability, elution and antimicrobial spectrum. This study showed its acceptable effects on the tensile mechanical properties of four common low viscosity bone cements.

Clinical use of vancomycin impregnated PMMA has been reported for salvage of infected total knee
Tensile properties of cured low viscosity bone cements

arthroplasty (12), and is now currently used in our institution for cemented hip and knee arthroplasty.
