The Formal Model of a Pattern Browsing Technique

Jan Hidders   Cora Hoskens   Jan Paredaens

Abstract

In this report we introduce a general browsing model that describes intuitive ideas about browsing. In this model it is assumed that the database scheme, as well as the instance of the database are represented by graphs. The most important browsing step in this model is the pattern step. It is based upon finding subgraphs in the instance matching a pattern and supplied with a browsing condition that links it to previous steps. This allows the user to visually specify a browsing step based upon the results of previous steps. Other browsing steps and operators in the model allow the user to randomly select some subgraphs found by a step, replace an old browsing step with a new one or undo some of the last browsing steps. After presenting the model we compare its expressive power with that of the relational algebra.
1 Introduction

This paper introduces a browsing model. Browsing provides a means to investigate the contents of a database in a special way. It adds to querying the possibility to reuse former results. It is like moving around in the database by specifying intermediate results and using these to get more specific ones. In a sequence of steps the user tries to get closer to the information he wants to get.

What characterizes browsing, is that it is an interactive and iterative process of specifying queries and investigating the results of those queries in order to be able to state new ones. This is particularly useful when a user does not know exactly what he is looking for, or how to access the information he is looking for.

An example of a browsing facility is available in Smalltalk [8]. Smalltalk provides the possibility to wander around the class structure in order to find the particular class that the user is looking for. The classes are ordered in a tree structure and by means of browsing one can go from one class to one of its subclasses. Without this possibility it would be very hard to find the classes of interest.

Another way of browsing is available in hypertext documents [7]. In a hypertext, links are provided to other (parts of) documents which in some way or another are related to the current document. By choosing the right links, the user tries to find the document he is interested in. World Wide Web is a very nice example of a (world wide) hypertext [2]. Both examples show the characteristic of browsing: the use of intermediate results in order to get the required result.

This paper does not describe some new innovative browsing technique. It provides a general model to describe intuitive ideas about browsing [3], [4].

In this particular browsing model it is assumed that the database scheme, as well as the instances of the database are represented by graphs, such as in the GOOD model [1], [5], [6]. In this model, the nodes of the graph represent objects while the edges represent the properties of and the relationships between the objects.

A pattern is also a graph, and can be used to select subsets of an instance by the notion of pattern matching. This means that every subgraph of an instance that matches the pattern is selected. Such a subgraph is called an embedding.

With the pattern browsing technique, every possible action that the user can take is called a browsing statement. Browsing statements can be divided into browsing steps and browsing operators. There are two different steps in the model and two different operators. Actually, the steps are the elementary browsing statements. They provide the user with all necessary actions to enable him to browse. The operators, on the other hand, are meant to ease the task of the user. We first discuss the two possible browsing steps.

First of all, embeddings can be selected by specifying a pattern. As such it is a pattern matching step, or pattern step for short. The nodes in the pattern are labeled, and they can also be given a condition. Such a condition is called a node condition. By means of these node conditions, the user can restrict the subgraphs that are selected. The node conditions put an extra restriction on embeddings. Thus, an embedding is a subgraph that matches the pattern and fulfills the node conditions.

However, in the context of browsing a more general condition can apply to a pattern step, which is therefore called the browsing condition. This condition links the pattern to embeddings found in previous steps, and is therefore essential for the process of browsing. In such a way, it is possible to combine the results of several steps by combining conditions, that refer to different steps, into one condition.

Secondly, it is possible to select a set of embeddings amongst the ones that resulted from a previous step. Such a step is called the selection step. That way it is possible to select only the embeddings that seem interesting to the user. It narrows down future searches.

Besides these two steps, there are two operators. Each of these operators changes, in fact, a browsing program, which is a sequence of browsing steps. The first one, the change operator changes one step of the program, which may affect the result of this step and also of later steps.
that refer to that step. The second one, on the other hand, the rollback operator, rolls back one or more browsing steps.

The operators are introduced because they add to the intuitive ideas about browsing. Browsing means investigating the contents of the database in an interactive manner. The possibility to backtrack (as provided by the change and rollback operator), and retrace steps (as with the change operator) can be part of that process. Including the operators makes it possible to have more user-friendly browsing sessions.

It is possible to show the results of subsequent statements in a tree, as will be shown later in this paper. The embeddings that are found in the pattern and selection steps make up the nodes of this tree, while each edge is labeled with the step label. Each of these steps adds one layer to the browsing tree. The layer that contains the result of step $p$ is called layer $p$. The browsing tree is a visual aid for the representation of the result. The browsing tree not only shows the results of each step, but also shows (by means of the edges) the dependencies between nodes in different steps.

Every node in a pattern has a node label. However, we presume that the nodes of a pattern are linearly ordered and that it is therefore also possible to speak about e.g. the third node of a pattern. Consequently, embeddings can be represented by unlabeled tuples. Also, an infinite countable set $L = \{10, 11, 12, \ldots \}$ of step labels is presumed, with 10 denoting step 0.

## 2 Definition of the Pattern Browsing Model

### 2.1 An example

First an informal example is given that illustrates the notion of browsing and the intended meaning of the different statements. In this example steps as well as operators are used. Note that each time an operator is encountered in the program, this operator can be replaced by rewriting the steps of the program according to this operator.

![Figure 1: A simple instance](image)

Figure 1: A simple instance
Example 1. This example uses a small instance, given in Figure 1. In this instance the objects have an identification label, which makes it possible to distinguish between them.

The instance represents four persons with their name, address and age (if those are known) together with their child-relationships.

---

Step 1 (pattern step): Select the nodes with pattern:

```
 n1  address  n2  has_child  n3
  |________|________|________|
  |  string |  Person  |  Person |
  v          |________|________|
    |_______|________|
    | age  |  number |
    v
    n4 ≥ 40
```

This query asks for all persons that are at least 40 years of age, together with their address and one of their children.

The result of this step is set of embeddings that match the pattern. Every embedding can therefore be represented by a (address, person, person, age)-tuple. The result can be represented by the following table:

<table>
<thead>
<tr>
<th>address</th>
<th>person1</th>
<th>person2</th>
<th>age</th>
</tr>
</thead>
<tbody>
<tr>
<td>Antwerp</td>
<td>p_1</td>
<td>p_2</td>
<td>40</td>
</tr>
<tr>
<td>Antwerp</td>
<td>p_1</td>
<td>p_3</td>
<td>40</td>
</tr>
</tbody>
</table>
Step 2 (pattern step with pattern condition): Select the nodes with pattern:

\[
\begin{align*}
\text{n}_1 & \rightarrow \text{string} \rightarrow \text{n}_2 \rightarrow \text{Person} \rightarrow \text{address} \rightarrow \text{n}_3 \rightarrow \text{string} \\
\end{align*}
\]

and condition: node \(n_2\) matches node \(n_3\) of step 1, and node \(n_3\) matches node \(n_1\) of step 1.

Node \(n_2\) of the instance \((\text{Person})\) has to match node \(n_3\) of a tuple of step 1, which is the 'child' object of that pattern. In the same way, node \(n_3\) of the instance \((\text{Address})\) has to match node \(n_1\) of the same tuple, which is the 'address of the parent' of that pattern. This means that this query asks for all children who live at the same address of one of their parents, for those parents that were selected in step 1, together with their name and address.

This step will have the following table as result:

\[
\begin{array}{c|c|c}
\text{n}_1 & \text{n}_2 & \text{n}_3 \\
\hline
\text{Piet} & \text{p}_1 & \text{Antwerp} \\
\end{array}
\]

Step 3 (change operator): Change the pattern of step 1 into the following one:

\[
\begin{align*}
\text{n}_1 & \rightarrow \text{string} \rightarrow \text{n}_2 \rightarrow \text{Person} \rightarrow \text{address} \rightarrow \text{n}_3 \rightarrow \text{Person} \\
\text{n}_4 & \rightarrow \text{age} \rightarrow \text{number} \rightarrow n_4 \geq 20 \\
\end{align*}
\]

This operator will change the original step 1. This adapted version of step 1 asks for all persons that are at least 20 years of age, together with their address and one of their children. Step 1 and 2 are executed again, which will now result in the following tables:

**Step 1:**

<table>
<thead>
<tr>
<th>(n_1)</th>
<th>(n_2)</th>
<th>(n_3)</th>
<th>(n_4)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Antwerp</td>
<td>p._1</td>
<td>p._2</td>
<td>40</td>
</tr>
<tr>
<td>Antwerp</td>
<td>p._1</td>
<td>p._3</td>
<td>40</td>
</tr>
<tr>
<td>Antwerp</td>
<td>p._2</td>
<td>p._4</td>
<td>25</td>
</tr>
</tbody>
</table>

**Step 2:**

<table>
<thead>
<tr>
<th>(n_1)</th>
<th>(n_2)</th>
<th>(n_3)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Piet</td>
<td>p._3</td>
<td>Antwerp</td>
</tr>
<tr>
<td>Kees</td>
<td>p._4</td>
<td>Antwerp</td>
</tr>
</tbody>
</table>
Step 4 (selection step): Select the following embedding from the result of step 2:

<p>| | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Kees</td>
<td>p.4</td>
<td>Antwerp</td>
</tr>
</tbody>
</table>

This query can be formulated as follows: select from the embeddings that were found in step 2, exactly the ones given in the table.

The result of this step is that the given embeddings are selected. This narrows down future searches as will be visualised when the results are presented in a browsing tree further on in this paper.

The result of this step is given by the following table:

<p>| | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Kees</td>
<td>p.4</td>
<td>Antwerp</td>
</tr>
</tbody>
</table>

Now imagine that the user finds that he made the wrong selection in step 4. What he can do now, is either change it with a change operator, or throw away step 4 altogether by means of a rollback operator. Imagine that he wants to do the latter. Step 5 would then look like:

Step 5 (rollback operator): Now roll back all actions from step 4 on.

This query can be translated as: throw away step 4.

The result of this step is that the result of step 4 is removed, and can no longer be used in subsequent steps.

This concludes the illustration of the different browsing steps.

2.2 Syntax of a browsing program

In this section, the syntax of a browsing program is described. First of all, the notion of a primitive browsing program is introduced. A primitive browsing program uses only (pattern and selection) steps. The syntax of the steps is given. Then, the notion of a non-primitive browsing program is introduced, in which also the change and rollback operators can be used. Also, the syntax of the operators is given.

The example given in the introduction is then worked out in the proper syntax. Finally, the result of the example is presented in a browsing tree.

2.2.1 Primitive statements: pattern step and selection step

Definition 1 A pattern step has the following syntax:

1 : (pat p, cond c);

and is defined by

- a label l
- a pattern p
- a pattern condition c ∈ C, where C is defined by:
C ::= (n_{i_1}, n_{i_2}, ..., n_{i_k}) ::= (\text{anc}_P (n_{j_1}, n_{j_2}, ..., n_{j_k})) |
(n_{i_1}, n_{i_2}, ..., n_{i_k}) ::= (\text{exist}_P (n_{j_1}, n_{j_2}, ..., n_{j_k})) | \text{NOT} (C) | (C \text{ AND } C) | (C \text{ OR } C) \ |
where n_{i_1}, n_{i_2}, ..., n_{i_k} and n_{j_1}, n_{j_2}, ..., n_{j_k} are node labels, and \text{l'} is a step label.

This step is essentially a pattern matching step with a possibility to include a pattern condition \text{c}.

All nodes of the pattern are labeled with an identifier. In the pattern, each node may have a node condition. The syntax of the node condition of a node \text{n}_i is as follows:

\[ NC ::= n_i = e | n_i \leq e | n_i < e | n_i \geq e | n_i > e | \text{NOT} (NC) | (NC \text{ AND } NC) | (NC \text{ OR } NC) \]

where expression \text{e} is either a node label, a value, or an numerical expression (in which the binary operators +, -, *, / can be used) including a node label.

When a node is given a node condition, the value of this node is restricted. This means that each node in an embedding fulfills its condition. If \text{e} contains a node label \text{n}_j it means that the value of \text{n}_i is dependent on the value of \text{n}_j.

An example of a pattern with node-conditions is given in Figure 2. This pattern specifies persons who live in Antwerp and who are not older than 50 years, who have a child who is at least 30 years younger than him/herself. The result will consist of tuples of the form (name, address, person, age, person, age) for embeddings that match the pattern. They fulfill the following conditions:

"Person n.3 lives in Antwerp, is less than 50 years old, and his/her stepchild n.5 is at least 30 years younger than him/herself."

Figure 2: A pattern with node-conditions

In a pattern step \text{l} : (\text{pat } p, \text{ cond } c), label \text{l} is used to identify the step within the program. Pattern condition \text{c} links the pattern to the selected embeddings of one or more preceding steps. It consists of subconditions of the form: ((n_{i_1}, n_{i_2}, ..., n_{i_k}) ::= (\text{anc}_P (n_{j_1}, n_{j_2}, ..., n_{j_k}))) and ((n_{i_1}, n_{i_2}, ..., n_{i_k}) ::= (\text{exist}_P (n_{j_1}, n_{j_2}, ..., n_{j_k}))). Each subcondition specifies for certain nodes of the pattern, which nodes of previously selected embeddings they have to match. There is a subtle difference between the meaning of the first and the second subcondition, which is explained later in the paper. Basically, they both say that nodes n_{i_1}, n_{i_2}, ..., n_{i_k} have to match nodes n_{j_1}, n_{j_2}, ..., n_{j_k}, respectively, of an embedding of step \text{l'}. Later on in the paper, we will explain the semantics of \text{anc} and \text{exist} in more detail.

The result of a pattern step is the set of embeddings of the pattern that satisfy the pattern condition.

**Definition 2** A selection step has the following syntax: \n
\[ l : (label \ l', select \ S), \]

and is defined by
The meaning of a selection step is that of the embeddings, found in step \( l' \), the ones in set \( S \) are selected. The idea behind a selection step is that the user selects the embeddings that he finds interesting and wants to continue with. Generally, it narrows down the search path for future steps. The pattern of selection step \( l \) is defined as the pattern of step \( l' \). This means is that selection step \( l \) inherits the pattern of step \( l' \). This pattern is needed when a future pattern step refers to step \( l \) in its pattern condition.

In the remainder of this paper we identify a step by its label, i.e. step \( l \) is short for the step with label \( l \).

### 2.2.2 Primitive browsing programs

We introduce the notion of a closed primitive browsing program. A primitive browsing program is a sequence of browsing steps that fulfill certain conditions. These conditions make sure that each step encountered during the evaluation of the program has a defined meaning. A closed primitive browsing program is a browsing program that starts from scratch. An open primitive browsing program, on the other hand, takes an existing browsing program as input, and then adds one or more steps to it.

A pattern step with a non-empty pattern condition refers to a previously defined step in a browsing program. The embeddings of the pattern step then have to match an embedding of the referenced step. A selection step also refers to a previously defined step in a browsing program. The embeddings of its selection set are taken from the referenced step. To define the syntax of a primitive browsing program it is therefore necessary to know the set of steps that a pattern or selection step \( l \) can refer to. This is known as the **set of referencable labels of step \( l \)**.

**Definition 3** The set of referencable labels of step \( l_i \) in the context of a primitive browsing program \([l_0, l_1, \ldots, l_{i-1}, l_i, \ldots, l_n]\), is the set of labels that \( l_i \) may refer to in the program, and is defined as follows:

\[
srl([l_0, l_1, \ldots, l_{i-1}, l_i, \ldots, l_n], l_i) = \{ l_0, l_1, \ldots, l_{i-1} \}
\]

**Definition 4** A closed primitive browsing program is a finite list of browsing steps, for which the following holds:

- Every step in the list has a unique step label.
- If a pattern step \( l \) has a pattern condition containing a subcondition of the form
  \((n_{i_1}, n_{i_2}, \ldots, n_{i_k}) := (\text{and}(n_{j_1}, n_{j_2}, \ldots, n_{j_k}))\) or
  \((n_{i_1}, n_{i_2}, \ldots, n_{i_k}) := (\text{exist}(n_{j_1}, n_{j_2}, \ldots, n_{j_k}))\) then
    - \( l' \) has to be in the set of referencable labels of \( l \)
    - \( n_{i_1}, n_{i_2}, \ldots, n_{i_k} \) are unique node labels of the pattern of step \( l \)
    - \( n_{j_1}, n_{j_2}, \ldots, n_{j_k} \) are node labels of the pattern of step \( l' \).
- For every selection step \( l \) : \((\text{label } l', \text{select } S)\) it holds that
  - \( l' \) has to be in the set of referencable labels of \( l \)
  - selection set \( S \) only contains embeddings that are in the result of step \( l' \).

**Definition 5** An open primitive browsing program is a consecutive subsequence \([l_{i_1}, \ldots, l_k]\) of a closed primitive browsing program \([l_0, \ldots, l_i, \ldots, l_k, \ldots, l_n]\).
2.2.3 Operators: change and rollback operator

Definition 6 A change operator has the following syntax:

\[
\text{change } I \text{ into } s;
\]

where

\[
s \text{ is a pattern step } I : (\text{pat } p, \text{cond } c), \text{ or a selection step } I : (\text{label } l', \text{select } S).
\]

The meaning of the change operator is that it changes step \(I\). The existing step \(I\) is replaced by the new step, identified by the change operator. The idea behind a change operator is, that the user can backtrack to a certain point in a program to change a move, and then retrace the rest of the steps.

Definition 7 A rollback operator has the following syntax:

\[
\text{rollback } I;
\]

where

\[
I \text{ is a step label.}
\]

The meaning of a rollback operator is that it identifies a certain position in the program (by means of the step label). The program then rolls back all steps up to and including step \(I\). It is like backtracking to the step that precedes step \(I\).

Note that operators do not have a step label. They do not need one, because statements never refer to operators.

2.2.4 Non-primitive browsing programs

Non-primitive browsing programs are browsing programs in which steps as well as operators can be used. Therefore it is a sequence of statements. A non-primitive browsing program can be rewritten to a primitive browsing program. Therefore, primitive browsing programs have the same expressive power as non-primitive browsing programs.

Operators refer to browsing steps, which are identified by their label. Change operators refer to the step that they change, and rollback operators refer to the first step that has to be undone. To define the syntax of a non-primitive browsing program, it is therefore necessary to define a set of labels that an operator can refer to. This is known as the set of referencable labels of the operator. Since we already defined the set of referencable labels of a browsing step, we can now define the set of referencable labels of an arbitrary statement, in the context of a non-primitive browsing program.

Definition 8 The set of referencable labels of statement \(s_i\), in the context of a browsing program, is the set of labels that \(s_i\) may refer to in the program, and is defined as follows:

\[
\begin{align*}
srl([l : (\text{pat } p, \text{cond } c)]) &= \{l\}, \\
\text{srl}([s_0, \ldots, l : (\text{pat } p, \text{cond } c), s_i, \ldots, s_n], s_i) &= \\
&\quad \text{srl}([s_0, \ldots, l : (\text{pat } p, \text{cond } c)], l : (\text{pat } p, \text{cond } c)) \cup \{l\}, \\
\text{srl}([s_0, \ldots, l : (\text{label } l', \text{select } S), s_i, \ldots, s_n], s_i) &= \\
&\quad \text{srl}([s_0, \ldots, l : (\text{label } l', \text{select } S)], l : (\text{label } l', \text{select } S)) \cup \{l\}, \\
\text{srl}([s_0, \ldots, \text{change } l \text{ into } s, s_i, \ldots, s_n], s_i) &= \\
&\quad \text{srl}([s_0, \ldots, \text{change } l \text{ into } s], \text{change } l \text{ into } s), \\
\text{srl}([s_0, \ldots, \text{step } l, \ldots, \text{rollback } l, s_i, \ldots, s_n], s_i) &= \\
&\quad \text{srl}([s_0, \ldots, \text{step } l], \text{step } l), \\
\text{where } l &\in \text{srl}([s_0, \ldots, \text{step } l, \ldots, \text{rollback } l], \text{rollback } l).
\end{align*}
\]
The set of referencable labels of a statement $s_i$ in the context of a browsing program is determined by considering the previous statement $s_{i-1}$. If $s_{i-1}$ is a step, then $srl(s_i)$ is equal to the union of $srl(s_{i-1})$ and the label of $s_i$. If $s_{i-1}$ is a change operator, then $srl(s_i)$ is equal to $srl(s_{i-1})$. The last possibility is that $s_{i-1}$ is a rollback operator that rolls back all statements up and including $s_i$. Then, $srl(s_i)$ is equal to $srl(s_i)$. If, however, a statement has no predecessor it means that the statement itself is a pattern step, because a browsing program always starts with a pattern step. Therefore, the set of referencable labels of a pattern step in the context of itself, is defined.

**Definition 9** A closed non-primitive browsing program is a finite list of browsing statements, for which the following holds:

1. Every step in the list has a unique step label.
2. If a pattern step $l$ has a pattern condition containing a subcondition of the form
   \[(n_{i_1}, n_{i_2}, \ldots, n_{i_k}) := (\text{ancestor}(n_{j_1}, n_{j_2}, \ldots, n_{j_k})), \text{or} \]
   \[(n_{i_1}, n_{i_2}, \ldots, n_{i_k}) := (\text{exist}(n_{j_1}, n_{j_2}, \ldots, n_{j_k})) \]
   then
   - $l'$ is an element the set of referencable labels of $l$,
   - $n_{i_1}, n_{i_2}, \ldots, n_{i_k}$ are unique node labels of the pattern of step $l$,
   - $n_{j_1}, n_{j_2}, \ldots, n_{j_k}$ are node labels of the pattern of step $l'$.
3. For every selection step $l : (\text{label } l', \text{select } S)$ it holds that
   - $l'$ is an element of the set of referencable labels of $l$,
   - selection set $S$ only contains embeddings that are in the result of step $l'$.
4. For every change operator change $l$ into \(l : (\text{pat } p, \text{cond } c)\), it holds that
   - $l$ is an element of the set of referencable labels of this change operator,
   - step $l$ is a pattern step $l : (\text{pat } p', \text{cond } c')$ such that $p'$ at most differs from $p$ in its relationships between its nodes and in its node conditions,
   - $l : (\text{pat } p, \text{cond } c)$ conforms to rule [2].
5. For every change operator change $l$ into \(l : (\text{label } l', \text{select } S)\) it holds that
   - $l$ is an element of the set of referencable labels of this change operator,
   - step $l$ is a selection, step $l : (\text{label } l', \text{select } S')$, which therefore also selects embeddings from step $l'$,
   - $l : (\text{label } l', \text{select } S)$ conforms to rule [3].
6. For every rollback operator rollback $l$ it holds that $l$ is an element of the set of referencable labels of this rollback operator.

**Definition 10** An open non-primitive browsing program is a consecutive subsequence $s_i, \ldots, s_k$ of a closed non-primitive browsing program \(\{s_0, \ldots, s_i, \ldots, s_k, \ldots, s_n\}\).

**Example 2** Here, Example 1 is worked out in the notation of the pattern browsing technique. It is a closed, non-primitive browsing program.

```
11:
<pat
---
```
, cond \( T > \),

12:
<pat
---

, cond \( (n2, n3) :: = (anc[11](n3,n1)) \),

---

change \( l1 \) into

----

\( l1 \):
<pat
---

, cond: \( T > \),

---
The resulting browsing trees of executing respectively the first to fifth statement of Example 2 are given in Figures 3, 4, 5, 6, and 7. The edges of each layer in a browsing tree are labeled with the corresponding step label. Executing the rollback operation deletes layer $l_3$ as shown by the cutting edge. The result of a subsequent pattern or selection step, would then be drawn in level 3 of the browsing tree.
2.3 Semantics of a browsing program

In this section the exact meaning of a browsing program is given, by means of its semantics. First, the definition of a browsing tree is given. A browsing tree provides the possibility to visualize the result of a browsing program. There are different ways to represent the results in the browsing tree. For instance, edges can be labeled with a step label, with a step label and the pattern of the step, or with the complete step. Also, the resulting embeddings can be represented as a tuple or as a graph. In this model, the edges are labeled with a step label and the pattern of the step. This makes it possible for other steps to refer to a step (and its pattern) in the browsing tree.

A primitive browsing program is made up of individual browsing steps, therefore the semantics of these steps is given. The semantics of the different steps is given with respect to a certain instance and a browsing tree. Then the semantics of a browsing program is given in terms of the semantics of the individual steps. Further, it is shown how a non-primitive browsing program can be translated into a primitive browsing program.
2.3.1 Browsing trees

The result of a browsing program can be shown in a tree: the browsing tree. Every step extends the browsing tree with a new layer. For each node in the bottom layer a (possibly empty) set of embeddings is added to the tree. Which embeddings are in this set, depends on the step itself, and of the embeddings in layers of steps that are referenced by in this step. A change operator backtracks to a certain layer, changes that step and then retraces its steps back to the bottom layer. A rollback operator rolls back a sequence of executed statements, up to and including the step indicated by the operator. In the browsing tree, this means that a rollback operator removes the layer of the indicated step, and all layers beneath it.

Definition 11 A browsing tree is a labeled tree where each edge is labeled with the label and the pattern of a step, and where each node is labeled with an embedding. Furthermore, it must hold that:

- The root is labeled with the empty embedding.
- Edges are labeled with the same step label if and only if they are on the same level.
- Embeddings in a layer of the browsing tree are embeddings of the pattern of that layer.
- Every node of the tree can be uniquely identified by the list of edge and node labels that are encountered on the path from the root to that node.

The browsing tree that consists of only the root is called the empty browsing tree or \(bt_0\). The expression \(\text{result}(bt, l)\) represents the set of nodes in the browsing tree \(bt\) that are the result of step \(l\), except for \(\text{result}(bt, 0)\) which represents the root of \(bt\).

2.3.2 Semantics of the pattern and selection step

Definition 12 The semantics of a pattern step is a partial function that given a pattern step, an instance and a browsing tree determines the updated browsing tree.

\[\text{sp}(l : (p, c), i, bt)\] is defined whenever

- label \(l\) does not yet have a layer in \(bt\), and
for every subcondition in \( c \) of the form \((n_{i_1}, n_{i_2}, \ldots, n_{i_k}) \) of \((n_{j_1}, n_{j_2}, \ldots, n_{j_k})\)

or \((n_{i_1}, n_{i_2}, \ldots, n_{i_k}) \) of \((n_{j_1}, n_{j_2}, \ldots, n_{j_k})\)

- \( n_{i_1}, n_{i_2}, \ldots, n_{i_k} \) are unique labels of a node of pattern \( p \),
- \( l' \) is the label of a layer in the browsing tree,
- \( n_{j_1}, n_{j_2}, \ldots, n_{j_k} \) are labels of a node of the pattern of layer \( l' \).

The result of \( \text{sps}(l : (\text{pat } p, \text{cond } c), i, bt) \) is a browsing tree that is a super-tree of \( bt \) in the following way. For each node \( n \) in the bottom layer of \( bt \), every embedding \( e \) of step pattern \( p \) into instance \( i \) is considered. If this embedding fulfills condition \( c \) a node \( m \) is added to \( bt \), as well as an edge from node \( n \) to node \( m \). Node \( m \) is labeled with embedding \( e \), and the edge is labeled with label \( l \) and pattern \( p \).

The super-tree thus has an extra (possible empty) layer \( l' \), as opposed to \( bt \).

Whether embedding \( e \) fulfills condition \( c \) is defined by induction on the condition:

- \((n_{i_1}, n_{i_2}, \ldots, n_{i_k}) \) holds if and only if

\( \exists \) embedding \( e' \in \text{result}(bt, l') \) such that \( \forall t \in \{1, 2, \ldots, k\} \) \( (e(n_{i_t}) = e'(n_{j_t})) \)

- \((n_{i_1}, n_{i_2}, \ldots, n_{i_k}) \) holds if and only if

\( \exists \) embedding \( e' \in \text{result}(bt, l') \) such that

1. \( \forall t \in \{1, 2, \ldots, k\} \) \( (e(n_{i_t}) = e'(n_{j_t})) \), and

2. \( e' \) lies on the path from tree node \( n \) to the root of \( bt \).

- \((c_1 \ \text{AND} \ c_2)\) holds if and only if \( c_1 \) holds and \( c_2 \) holds.

- \((c_1 \ \text{OR} \ c_2)\) holds if and only if \( c_1 \) holds or \( c_2 \) holds.

- \( \text{NOT}(c) \) holds if and only if \( c \) does not hold.

- \( \top \) holds always.

**Definition 13** The semantics of a selection step is a partial function that given a selection step and a browsing tree determines the new (extended) browsing tree.

\( \text{scs}(l : (\text{label } l', \text{select } S), bt) \) is defined whenever

- label \( l' \) has a layer in \( bt \), and

- label \( l \) does not yet have a layer in \( bt \), and

- \( \forall e : e \in S : e \in \text{result}(bt, l') \).

The result of \( \text{scs}(l : (\text{label } l', \text{select } S), bt) \) is a browsing tree that is a super-tree of \( bt \) in the following way. For each node \( n \) in the bottom layer of \( bt \) node \( n' \) is considered, where \( n' \) is defined as follows:

- \( n' \) lies on the path from \( n \) to the root of \( bt \), and

- \( n' \) is a node in layer \( l' \).

If the label of \( n' \) is an embedding \( e' \in \text{selection set } S \), then a new node \( m \) is added, as well as an edge from node \( n \) to node \( m \). Node \( m \) is labeled with embedding \( e' \), and the edge is labeled with \( l \) and the pattern of layer \( l' \).

The super-tree thus has an extra (possible empty) layer \( l' \), as opposed to \( bt \).
Semantics of a primitive browsing program

**Definition 14** The semantics of an open primitive browsing program is a partial function that given an open primitive browsing program, a browsing tree and an instance determines the new (extended) browsing tree.

Whether the result of \( \text{ sopb}([s_1, \ldots , s_k], bt, i) \) is defined, can be deduced by induction upon the structure of the browsing program:

- \( \text{ sopb}([s_1], bt, i) \) is defined if either \( s_1 \) is a pattern step and \( sps(s_1, i, bt) \) is defined, or \( s_1 \) is a selection step and \( scs(s_1, bt) \) is defined.

- \( \text{ sopb}([s_1, s_2, \ldots , s_k], bt, i) \) is defined if \( \text{ sopb}([s_1], bt, i) \) is defined and \( \text{ sopb}([s_2, \ldots , s_k], \text{ sopb}([s_1], bt, i), i) \) is defined.

This means that the function is defined if for every step \( s \), the step semantics function \( sps \) or \( scs \) (depending on whether it is a pattern or selection step) is defined in the context of the tree that this step takes as input tree. This is the tree that is created if the steps that precede \( s \) are executed with \( bt \) as original input tree.

The result of \( \text{ sopb}([s_1, \ldots , s_k], bt, i) \) is defined as follows:

\[
\text{ sopb}([], bt, i) = \text{ bt} \\
\text{ sopb}([s_1, s_2, \ldots , s_k], bt, i) = \text{ sopb}([s_2, \ldots , s_k], \text{ sopb}([s_1], bt, i), i) \text{ if } s_1 \text{ is a pattern step} \\
\text{ sopb}([s_2, \ldots , s_k], \text{ scs}(s_1, bt), i) \text{ if } s_1 \text{ is a selection step}
\]

**Definition 15** The semantics of a closed primitive browsing program is a function that given a closed primitive browsing program and an instance determines the browsing tree of the program.

In fact, the semantics is equal to the open browsing program semantics if it takes the closed browsing program together with the empty browsing tree (bt0, which consists only of the root) as input. The only difference is, that the well defined structure of a closed browsing program ensures that the semantics function exists.

Hence, \( \text{ sopb}([s_1, \ldots , s_n], i) = \text{ sopb}([s_1, \ldots , s_n], bt_0, i) \).

Semantics of a non-primitive browsing program

Instead of defining the semantics of a non-primitive program in terms of the semantics of its individual statements, a translation is given to a primitive browsing program. The semantics of a primitive browsing program which has been given earlier in this paper, can then be applied. The reason we can do this, is that each operator is, in fact, a short cut for rewriting an existing primitive browsing program to another primitive browsing program.

**Definition 16** The translation of a closed non-primitive browsing program \( \text{ trans} : \text{ CBP} \rightarrow \text{ CPBP} \) is a function that given a closed non-primitive browsing program cbp translates it to an equivalent closed primitive browsing program cpbp.

This function is defined by induction upon the structure of the browsing program. The result of \( \text{ trans}(\text{ obp}) \) is defined as follows:

\[
\text{ trans}([s_1, \ldots , l : (\text{ pat } p, \text{ cond } c), \ldots , s_k, \text{ change } l \text{ into } l : (\text{ pat' } p', \text{ cond' } c'), s_1, \ldots , s_n]) = \text{ trans}([s_1, \ldots , l : (\text{ pat } p', \text{ cond } c'), \ldots , s_k, s_1, \ldots , s_n])
\]

where \( s_1, \ldots , s_k \) are steps,

\[
\text{ trans}([s_1, \ldots , l : (\text{ label } l', \text{ select } s), \ldots , s_k, \text{ change } l \text{ into } l : (\text{ label' } l', \text{ select' } S'), s_1, \ldots , s_n]) = \text{ trans}([s_1, \ldots , l : (\text{ label } l', \text{ select' } S'), \ldots , s_k, s_1, \ldots , s_n])
\]

where \( s_1, \ldots , s_k \) are steps.
\[ \text{trans}([s_1, \ldots, s_i, \text{step } l, \ldots, s_k, \text{rollback } l, s_i, \ldots, s_n]) \]
\[ = \text{trans}([s_1, \ldots, s_i, s_i, \ldots, s_n]) \]
\[ \text{trans}([s_1, \ldots, s_n]), \text{where } s_1, \ldots, s_n \text{ are steps}, \]
\[ = [s_1, \ldots, s_n]. \]

Because closed non-primitive browsing programs have, by definition, a well defined structure, the above translation rules will always result in a closed primitive browsing program.

The translation function traverses to the first operator in the list of statements. If this is a change operator, it changes the indicated pattern or selection step, and then continues. The change operator is deleted from the list. If the first operator in the list is a rollback operator, the steps between the indicated step and the rollback operator are deleted from the list, as well as the rollback operator itself. The translation function is then repeated, with the new list of steps as input. This repeats itself until all steps in the list are primitive steps.

**Definition 17** The semantics of a closed non-primitive browsing program is a function that given a closed non-primitive browsing program determines the browsing tree of the program.

The semantics can now be defined in terms of the translation function as follows:

\[ \text{scb}([s_1, \ldots, s_n], l) = \text{scp} (\text{trans}([s_1, \ldots, s_n])). \]

This means that a closed non-primitive program is first translated to a closed primitive program. Then the semantics of a closed primitive program is applied to this primitive program.
3 The Expressiveness of the Model

In this section we will discuss the expressiveness of the browsing model. With expressiveness we mean the ability to calculate certain transformations. The browsing model will be compared with the relational algebra in several ways. We will consider only the model with primitive programs (consisting of steps only) since operations can be regarded as syntactic sugar. Also, we will not consider arithmetic in the node conditions because this would make the model incomparable with the relational model.

To be able to determine whether the browsing model is as expressive as the relational algebra and vice versa we have to establish what it means for one system of transformations to be as expressive as another.

**Definition 18** Let A and B be transformation systems and let \(im\) be a total mapping of the input domain of A to the input domain B and let \(om\) be a total mapping of the output domain of A to the output domain of B, as shown in Figure 8. A is as expressive as B under input mapping \(im\) and output mapping \(om\) if for every transformation \(g\) in B there is a transformation \(f\) in A such that \(om \circ f = im \circ g\). If the reverse holds we say that B can implement A under input mapping \(im\) and output mapping \(om\).

Whether the browsing model is as expressive as the relational algebra depends upon the chosen mappings. Another important factor is how we choose the input and output domain of the browsing model and what we consider to be the transformations that are defined by the system.

For the relational model these choices are fairly obvious:

**Input Domain** A set of relations.

**Output Domain** A single relation.

**Transformations** Those expressed by an expression of the relational algebra.

For the browsing model they are less obvious. The first system we will consider is the following:

**Input Domain** A browsing tree.

**Output Domain** The embeddings of the nodes in the bottom layer of the resulting browsing tree.

**Transformations** Those expressed by a an open browsing program.

This system is called \(PBM_1\) (Pattern Browsing Model 1). Now we know what the system is we can determine the mapping of the input and the output domains. The input mapping maps the layers of the browsing tree to tables containing the embeddings of the nodes of those layers. There will be a table for every layer and its name will the label of that layer. This mapping is
Theorem 1 Under input mapping \( \text{im}_1 \) and output mapping \( \text{om}_1 \) it holds that \( \text{PBM}_1 \) is as expressive as the relational algebra.

Proof: The proof is given by induction upon the algebra expression. We will show that the theorem holds for every individual algebra operator. Because we can concatenate them into one program it follows that any algebra expression can be simulated. It is presumed that every step receives a fresh step label that is not in the browsing tree. The exact order is not relevant but it should hold that the simulations of subexpressions precede the simulation of the comprising expression.

The translation of algebra operators in steps is demonstrated in Figure 10. Notice that in this proof we presume that there is only one node label \( A \). It is possible to generalize the proof for more node labels but this would complicate the proof. Note also that we do not consider relational algebra operations such as \( \sigma_{<t}(R) \) but it is easy to see how they might be simulated with the help of node conditions.

The expressiveness of \( \text{PBM}_1 \) as stated in Theorem 1 is slightly “crude”. It says something about the manipulation of complete layers whereas in the browsing model with every step an extension is calculated for every separate branch. This explains why the anc-references were not really needed for the simulation, because they refer to the branch-specific embeddings. It is possible to define a more subtle expressiveness by extending the input domain of \( \text{PBM}_1 \) with a branch identification and define the output as the embeddings of the nodes at the bottom of the tree that was added to this branch. The relational algebra expression would then not only operate on tables containing the layers but also on tables containing the (single) embedding of every layer in the branch. The question whether the browsing model is as expressive as the relational algebra in this way, is still open.

Up to now we have regarded the expressiveness of the browsing model as a manipulation language for browsing trees. Yet, the user is only interested in the browsing tree as an intermediate result and, ultimately, is more interested in the final result (a set of embeddings) he can obtain starting with a certain instance. Therefore, it may be more interesting to see which sets of embeddings can be found given a certain instance and starting with the empty browsing tree. For this purpose we define \( \text{PBM}_2 \):

**Input Domain** An instance.

**Output Domain** The embeddings of the nodes in the bottom layer of the resulting browsing tree.

**Transformations** Those expressed by a closed browsing program.

The input mapping \( \text{im}_2 \) maps an instance (a labeled graph) to unary and binary tables. For every node label there will be an unary table of that name containing all the nodes in the instance.
\[ l_a \Rightarrow \text{pattern: } n_1 : [A] \ldots n_p : [A] \]
\[ \text{condition: } (m_1, \ldots, m_p) = \exists_{t_a}(n_1, \ldots, n_p) \]
where \( p \) is the arity of step \( l_a \) and \( m_1, \ldots, m_p \) are the nodes of step \( l_a \).

\[ \sigma_{n_i=v}(l_a) \Rightarrow \text{pattern: } n_1 : [A] \ldots n_p : [A] \]
\[ \text{condition: } T \]
where \( v \) is a printable value and \( n_1, \ldots, n_p \) are the nodes of step \( l_a \).

\[ \pi_{n_1, \ldots, n_p}(l_a) \Rightarrow \text{pattern: } n_1 : [A] \ldots n_p : [A] \]
\[ \text{condition: } (n_1, \ldots, n_p) = \exists_{t_a}(n_1, \ldots, n_p) \]

\[ \rho_{n_i=m}(l_a) \Rightarrow \text{pattern: } n_1 : [A] \ldots n_{i-1} : [A] m : [A] n_{i+1} : [A] \ldots n_p : [A] \]
\[ \text{condition: } (n_1, \ldots, n_{i-1}, n_i, n_{i+1}, \ldots, n_p) = \exists_{t_a}(n_1, \ldots, n_{i-1}, m, n_{i+1}, \ldots, n_p) \]
where \( n_1, \ldots, n_p \) are the nodes of step \( l_a \).

\[ (l_a \land l_b) \Rightarrow \text{pattern: } m_1 : [A] \ldots m_p : [A] \]
\[ \text{condition: } (n_1, \ldots, n_p) = \exists_{t_a}(n_1, \ldots, n_p) \land (n_1', \ldots, n_p') = \exists_{t_b}(n_1', \ldots, n_p') \]
where \( n_1, \ldots, n_p \) and \( n_1', \ldots, n_p' \) are, respectively, the nodes of step \( l_a \) and step \( l_b \), and \( \{m_1, \ldots, m_p\} \) is the union of these two sets.

\[ (l_a - l_b) \Rightarrow \text{pattern: } n_1 : [A] \ldots n_p : [A] \]
\[ \text{condition: } (n_1, \ldots, n_p) = \exists_{t_a}(n_1, \ldots, n_p) \land \neg ((n_1, \ldots, n_p) = ) = \exists_{t_b}(n_1, \ldots, n_p) \]
where \( n_1, \ldots, n_p \) are the nodes of step \( l_a \) and step \( l_b \).

\[ (l_a \cup l_b) \Rightarrow \text{pattern: } n_1 : [A] \ldots n_p : [A] \]
\[ \text{condition: } (n_1, \ldots, n_p) = \exists_{t_a}(n_1, \ldots, n_p) \lor (n_1, \ldots, n_p) = \exists_{t_b}(n_1, \ldots, n_p) \]
where \( n_1, \ldots, n_p \) are the nodes of step \( l_a \) and step \( l_b \).

Figure 10: Translation of relational algebra operators
with that label. For every edge label there will be a binary table of that name containing all the pairs of begin and end nodes of edges in the instance. The output mapping om₂ is the same as om₁ and maps the embeddings of the bottom layer nodes to a table containing exactly these embeddings.

**Theorem 2** Under input mapping im₂ and output mapping om₂ it holds that PBM₂ is as expressive as the relational algebra.

**Proof:** The edges and nodes can be encoded in the layer as, respectively, binary and unary embeddings. The first steps of the (closed) program will therefore be \( n₁ : [N] \) for every node label \( N \) and \( n₁ : [N₁] \overset{2}{\Rightarrow} n₂ : [N₂] \) for every edge label \( α \) allowed between the node labels \( N₁ \) and \( N₂ \). The rest of the program is constructed according to Theorem 1, performing the algebraic expression upon these layers. \( \square \)

An important difference between PBM₁ and PBM₂ is the injectivity of the input mapping im₂. This means that no information is lost during that mapping and that it is now a meaningful question to ask the dual question of Theorem 2, i.e., can the relational algebra implement PBM₂?

**Theorem 3** Under input mapping im₂ and output mapping om₂ it holds that the relational algebra can implement PBM₂.

Before we can give the proof of this theorem we need a lemma that says that the relational algebra can implement a single pattern step of the browsing model. Therefore we define PBM₂:

**Input Domain** An instance and a browsing tree.

**Output Domain** The extended browsing tree.

**Transformations** Those expressed by a single pattern step.

The input mapping im₂ maps the instance to unary and binary tables as im₂. Furthermore, the browsing tree is mapped a set of relations with for every layer a relation containing all the embeddings of that layer and a single relation representing the browsing tree limited to its bottom nodes and their ancestors. The relations representing a layer are named with the label of the layer they represent. Their column names will be the the nodes of the step of that layer. The relation representing (a part of) the browsing tree is named BT and its column names will be all \( lᵢ.nᵢ \) with \( lᵢ \) a label of a step of a layer in the browsing tree and \( nᵢ \) a node in the pattern of that step. This relation will contain a tuple for every node in the bottom layer of the browsing tree consisting of the joined embeddings that are encountered on the path from this node to the root of the browsing tree. An example is given in Figure 11 where the result is shown of applying im₂ to the browsing tree of Figure 11 (after the rollback operation). Note that the tables representing the layers are not simply projections of the table BT.

The output mapping om₂ maps the new browsing tree to a relation in the same way as im₂ maps the old browsing tree to BT.

**Lemma 4** Under input mapping im₂ and output mapping om₂ it holds that PBM₂ can be implemented by the relational algebra.

**Proof:** The pattern step that is to be implemented is \( l: (pat \ pᵢ, cond \ cᵢ) \). The relational algebra expression that will do this is constructed in 4 phases:

1. The first phase consists of construction the algebra expression \( emb \) that determines the embeddings of the pattern \( pᵢ \) in the instance without considering the node conditions. Let \( pᵢ \) be \( (N, E, λ) \) where \( λ \) is the function that gives the labels of nodes in \( N \) and edges in \( E \). For every node \( nᵢ \) in \( N \) we construct \( neᵢ = p#1−nᵢ(λ(nᵢ)) \). Note that \( λ(nᵢ) \) denotes here the unary table that belongs to the label \( λ(nᵢ) \) with the single column #1. For every edge
\( e_f \) in \( E \) we construct \( ee_{e_f} = \rho_{\#1 \ldots \#n_1}(\rho_{\#3 \ldots \#n_3}(\lambda(e_f))) \) where \( n_1 \) and \( n_3 \) are, respectively, the begin and end node of \( e_f \). Note that \( \lambda(e_f) \) denotes here the binary table that belongs to the label \( \lambda(e_f) \) with the two columns \( \#1 \) and \( \#2 \). Finally, the table of embeddings can be constructed by simply joining all the relations of the nodes and the edges: \( \text{emb} = (n_{e_1} \land \ldots \land n_{e_p}) \land (\text{ee}_{e_1} \land \ldots \land \text{ee}_{e_p}) \) where \( N = \{n_1, \ldots, n_p\} \) and \( E = \{e_1, \ldots, e_p\} \).

2. The second phase constructs the algebra expression \( \text{emb}_n \) that determines the set of embeddings that fulfill the node conditions. For this purpose we define the function \( C : AE \times NC \rightarrow AE \) where \( AE \) is the set of relational algebra expressions and \( NC \) is the set of node conditions, such that \( C(\text{emb}, c) \) is the algebra expression that gives all the embeddings that fulfill node condition \( c \). It is defined with induction upon the condition:

(a) \( C(ae, c) = ae \) if the condition \( c \) is empty.
(b) \( C(ae, n \land m) = \sigma_{n, \theta m}(ae) \) where \( \theta \) is either \( =, \leq, <, \geq \) or \( > \).
(c) \( C(ae, \text{NOT}(c)) = ae - C(ae, c) \).
(d) \( C(ae, (c_1 \land c_2)) = C(ae, c_1) \cap C(ae, c_2) \).
(e) \( C(ae, (c_1 \lor c_2)) = C(ae, c_1) \cup C(ae, c_2) \).

The complete expression \( \text{emb}_n \) now has the form \( C(\text{emb}, c_1) \cap \ldots \cap C(\text{emb}, c_p) \) where \( c_1, \ldots, c_p \) are the node conditions of, respectively, the nodes \( n_1, \ldots, n_p \).

3. The third phase constructs the expression \( nbt \) that renames the columns of the result of \( \text{emb}_n \) to appropriate names for the browsing tree representation (by prefixing \( l \), the label of the step) and joins the result with the original browsing tree representation \( (BT) \).

\[ nbt = BT \bowtie (\rho'_{n_1 \rightarrow l_1 \times \ldots \times \rho'_{n_p \rightarrow l_p \times \text{emb}_n} \ldots )) \]

4. The fourth phase constructs the final expression that selects from the result of \( nbt \) those tuples that contain embeddings that fulfill the pattern condition \( c_f \). As in the second phase we define a function \( C' : AE \times PC \rightarrow AE \) where \( PC \) is the set of pattern conditions, such that \( C'(\text{emb}_n, c) \) selects from the result of \( \text{emb}_n \) those tuples that contain embeddings that fulfill the pattern condition \( c \). It is defined with induction upon the condition:

(a) \( C'(ae, T) = ae \)
(b) \( C'(ae, (n_1, \ldots, n_r)) := \text{AND}(m_1, \ldots, m_r) = \sigma_{i_1, n_1 = i_1} \ldots \sigma_{i_r, n_r = i_r}(ae) \ldots \)
(c) \( C'(ae, (n_1, \ldots, n_r)) := \text{EXIST}(m_1, \ldots, m_r) = \pi_{a_1, \ldots, a_s}(\sigma_{i_1, n_1 = m_1} \ldots \sigma_{i_r, n_r = m_r}(ae \land l')) \ldots \)
where \( a_1, \ldots, a_s \) are the column names of the result of \( \text{emb}_n \) and \( l' \) denotes the table containing the embeddings of the nodes in the layer with label \( l' \).
(d) \( C'(ae, \text{NOT}(c)) = ae - C'(ae, c) \).
(e) \( C'(ae_1, (c_1 \text{ AND } c_2)) = C'(ae, c) \cap C'(ae, c). \)

(f) \( C'(ae_1, (c_1 \text{ OR } c_2)) = C'(ae, c) \cup C'(ae, c). \)

The final relational algebra expression that simulates step 1 is now given by \( C'(nbt, c_p). \)

Just like the pattern step can be simulated in the relational algebra it is also possible to simulate the choice step in the relational algebra. Therefore we define \( PBM_3' \) that is equal to \( PBM_3 \) except that the transformation are those expressed by a single choice step.

**Lemma 5** Under input mapping \( \text{im}_2' \) and output mapping \( \text{om}_2' \) it holds that \( PBM_3' \) can be implemented by the relational algebra.

**Proof:** The choice step that is to be implemented is \( l : (\text{label } l', \text{set } \{\eta_1, \ldots, \eta_q\}) \) where \( \eta_1, \ldots, \eta_q \) are all embeddings.

We will construct for every embedding \( \eta_i \) an expression \( ae_i \) that selects those tuples that have that embedding for step \( l' \):

\[ ae_i = \sigma_{\eta_i=n_1(n_1) \ldots \sigma_{\eta_i=n_p(n_p)}(BT) \ldots \text{ where } n_1, \ldots, n_p \text{ are the nodes of the pattern of step } l'. \]  

The final result can then be computed by taking the union of the tables found per embedding:

\[ ae_1 \cup \ldots \cup ae_q \]

With the last two lemmas it is now easy to prove the previous theorem.

**Proof:** (of Theorem 3) It is easy to see how a complete closed browsing program can be simulated in the relational algebra by concatenating the simulations of the individual steps and starting with a table \( BT \) that has no columns and contains only the empty tuple.

However, this simulation fails if there is a step that has no result i.e. no nodes are added to the browsing tree. This is because in the browsing model the results of a step are always placed under the bottom layer nodes i.e. the result of the last step that was not empty, whereas in the simulation \( BT \) remains empty once it has become empty. This problem is solved by testing after every step if the result is empty. If it is not then the simulation of the following steps proceeds normally, but if it is then the simulation proceeds as if this step never happened. This is possible because the expression \( \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \) with \( e_1, e_2 \) and \( e_3 \) algebra expressions, can be emulated in the relational algebra.

An objection against \( PBM_3 \) might be that its transformations always act upon unary and binary relations. In the relational algebra the arity of the input relations is in general not limited. Furthermore, it is well known that relational tables of arbitrary arity can be coded in graphs as shown in Figure 12. Here the top node represents the relation with element-edges to the nodes that represent the tuples in the relation. The tuple nodes have edges that each represent a field of the tuple, labeled with the name of the field and ending in the value of the field. This leads us to the definition of \( PBM_3' \):

**Input Domain** An instance consisting of graphs of the form shown in Figure 12 with \( N \) the name of the \( p \)-ary relation, \( T \) a special tuple label, \( a_1, \ldots, a_p \) the (distinct) column names of \( N \) and \( D_1, \ldots, D_p \) the corresponding (printable) domain types. Nodes with relation names are always uniquely identified by their label.

**Output Domain** The embeddings of the nodes in the bottom layer of the resulting browsing tree.

**Transformations** Those expressed by a closed browsing program.
The input mapping \( \text{img} \) maps an instance to a set of tables, one for every node with a relation name as its label. The relation will contain the tuples that are represented by the tuple nodes that they have \textit{element}-edges to. These tuples contain exactly those fields that are labels of edges leaving the tuple node. The values of those fields are the values of the printable nodes that these edges end in. The output mapping \( \text{omg} \) is the same as \( \text{om} \) and maps the embeddings of the bottom layer nodes to a table containing exactly these embeddings.

**Theorem 6** Under input mapping \( \text{img} \) and output mapping \( \text{omg} \) it holds that \( \text{PBM}_3 \) is as expressive as the relational algebra.

**Proof:** The proof is similar to that of Theorem 2. The first steps of the program will be the encoding of the relations in the layers. For this we can use the pattern that is given in Figure 12 followed by a step for projecting the relation node and tuple node away. This is done for every relation that is represented in the instance. Once the relations are encoded in the layers we can construct the rest of the closed program according to Theorem 1, for performing the algebraic expression upon these layers. \( \square \)
