Abstract

This paper revisits basic message response time analysis of controller area network (CAN). We show that existing message response time analysis, as presented in [10], is optimistic. Assuming discrete scheduling, the problem can be resolved by applying worst-case response time analysis for fixed-priority non-preemptive scheduling (FPNS) as described in [4].

2 Real-time scheduling models

This section describes a basic scheduling model for FPPS and a refined model for FPNS. Most of the definitions and assumptions of these models originate from [8].

2.1 Basic model for FPPS

We assume a single processor and a set $T$ of $n$ periodically released, independent tasks $\tau_1, \tau_2, \ldots, \tau_n$. At any moment in time, the processor is used to execute the highest priority task that has work pending.

Each task $\tau_i$ is characterized by a (release) period $T_i \in \mathbb{R}^+$, a computation time $C_i \in \mathbb{R}^+$, a (relative) deadline $D_i \in \mathbb{R}^+$, where $C_i \leq \min(D_i, T_i)$, and a phasing $\phi_i \in \mathbb{R}$. An activation (or release) time is a time at which a task $\tau_i$ becomes ready for execution. A release of a task is also termed a job.

The job of task $\tau_i$ with release time $\phi_i$ serves as a reference activation, and is referred to as job zero. The release of job $k$ of $\tau_i$ therefore takes place at time $a_{ik} = \phi_i + kT_i$, $k \in \mathbb{Z}$. The deadline of job $k$ of $\tau_i$ takes place at $d_{ik} = a_{ik} + D_i$. The set of phasings $\phi_i$ is termed the phasing $\phi$ of the task set $T$.

The response interval of job $k$ of $\tau_i$ is defined as the time span between the activation time of that job and its completion time $c_{ik}$, i.e. $[a_{ik}, c_{ik}]$. The response time $r_{ik}$ of job $k$ of $\tau_i$ is defined as the length of its response interval, i.e. $r_{ik} = c_{ik} - a_{ik}$. The worst-case response time $WR_i$ of a task $\tau_i$ is the largest response time of any of its jobs, i.e.

$$WR_i = \sup_{\phi,k} r_{ik}. \quad (1)$$

A critical instant of a task is defined as an (hypothetical)
For FPNS, critical instants are given by time points at which all tasks have a simultaneous release [8].

From this notion of critical instants, Joseph and Pandya [5] have derived that for deadlines within periods (i.e. $D_i \leq T_i$) the worst-case response time $WR_i^p$ of a task $\tau_i$ is given by the smallest $x \in \mathbb{R}^+$ that satisfies

$$x = C_i + \sum_{j<i} \left\lceil \frac{x}{T_j} \right\rceil C_j.$$  

(3)

To calculate worst-case response times, we can use an iterative procedure based on recurrence relationships [1]. The procedure starts with a lower bound.

$$WR_i^{(0)} = \sum_{j<i} C_j$$

$$WR_i^{(k+1)} = C_i + \sum_{j<i} \left\lceil \frac{WR_j^{(k)}}{T_j} \right\rceil C_j$$

The procedure is stopped when the same value is found for two successive iterations of $k$ or when the deadline $D_i$ is exceeded. In the former case, it yields the smallest solution of the recursive equation, i.e. the worst-case response time of $\tau_i$. In the latter case the task is not schedulable. Termination of the procedure is ensured by the fact that the sequence $WR_i^{(k)}$ is bounded (from below by $C_i$, and from above by $D_i$) and non-decreasing, and that different values for successive iterations differ by at least $\min_j C_j$.

The interested reader is referred to [6, 7, 9] for techniques to derive worst-case response times for arbitrary deadlines. The main difference with deadlines within periods is that for arbitrary deadlines the worst-case response time of a task is not necessarily assumed for the first job that is released at the critical instant.

3.2 Message response time analysis for CAN

In this section, we recapitulate basic message response time analysis for ideal CAN. To this end, we first present the update of [5] given in [10] to take account of tasks being non-preemptive. Next, we recapitulate how the updated analysis can be applied to CAN as described in [10]. The analysis assumes deadlines within periods, i.e. $D_i \leq T_i$.

The non-preemptive nature of tasks may cause blocking of a task by at most one lower priority task. The maximum
blocking $B_i$ of task $\tau_i$ by a lower priority task is equal to the longest computation time of a task with a priority lower than task $\tau_i$, i.e.
\[ B_i = \max_{j<i} C_j. \] (4)

The worst-case response time $\overline{WR}_i$ is given by
\[ \overline{WR}_i = w_i + C_i, \] (5)

where $w_i$ is the smallest $x \in \mathbb{R}^+$ that satisfies
\[ x = B_i + \sum_{j<i} \left( \frac{x + \tau_{\text{res}}}{\tau_j} \right) C_j. \] (6)

In this latter equation, $\tau_{\text{res}}$ is the resolution with which time is measured. To calculate $w_i$, an iterative procedure based on recurrence relationships can be used. An appropriate initial value of this procedure is $w_i^{(0)} = B_i + \sum_{j<i} C_j$.

Because scheduling messages on a CAN bus is analogous to scheduling tasks by fixed priorities, the analysis given above can be used to determine the worst-case message response time for CAN. A message $\mu_i$ has a period $T_i$, a worst-case transmission time $C_i$, and a (relative) deadline $D_i$, where $C_i$ is a function of the number of message bytes $b_i$ of $\mu_i$. On a CAN bus, one deals with time units as multiples of the bit-time, which is denoted as $\tau_{\text{bit}}$, i.e. $\tau_{\text{res}} = \tau_{\text{bit}}$ in (6). With a 1Mbit/sec bus, $\tau_{\text{bit}}$ is equal to 1 $\mu$s. The worst-case message response time can now be derived using equations (4), (5), and (6).

4 Counterexamples

The task characteristics of our first counterexample are given in Table 1. The table includes the worst-case response times of the example as determined by means of [10] and [4]. Note that the (processor) utilization factor $U$ of the task set $T_1$ is given by $U = \frac{\tau_1}{\overline{HC}} + \frac{\tau_2}{\overline{HC}} + \frac{\tau_3}{\overline{HC}} \approx 0.986$. This example will be used for illustration purposes.

We merely mention that the existing analysis is also optimistic for the example given in Table 2.
4.2 Discussion

Above, we have shown that even when deadlines are within periods, we cannot restrict ourselves to the response time of a single job of a task when determining the worst-case response time of that task under FPNS. The reason for this is that a job of task $\tau_i$ can defer the execution of higher priority tasks, which can potentially give rise to higher interference for subsequent jobs of task $\tau_i$. We observe that the origin of the problem is basically the same as described in [3] for the problem with existing analysis for worst-case response times for fixed-priority scheduling with deferred preemption (FPDS) with arbitrary phasing and deadlines within periods.

In [4], worst-case response time analysis is presented for FPNS with arbitrary deadlines, arbitrary phasing, and discrete (rather than continuous) scheduling [2]. For discrete scheduling, all task parameters are restricted to integers, and tasks are scheduled at integer times. For completeness, Lemma 6 and Theorem 15 of [4] are given below, with minor modifications to match our terminology and scheduling model. The lemma describes a critical instant for task $\tau_i$.

**Lemma 1** The worst-case response time of $\tau_i$ is found in a level-i busy period by releasing all tasks $\tau_j$ with $j \leq i$ simultaneously at time $t = 0$, and by releasing the longest task $\tau_k$ with $k > i$, if any, at time $t = -1$.

**Theorem 1** Given a task set $T$ consisting of $n$ tasks $\tau_1, \ldots, \tau_n$, the worst-case response time of any task $\tau_i$ is given by

$$WR_i^N = \max_{q=0,\ldots,Q} \{ w_{i,q} + C_i - qT_i \},$$

where

$$w_{i,q} = qC_i + \sum_{j<i} \left( 1 + \frac{w_{i,q}}{T_j} \right) C_j + \max_{k>i} \{ C_k - 1 \},$$

and $Q = \left\lfloor \frac{L_i}{T_1} \right\rfloor$, where $L_i$ is the length of the longest level-i busy period in non-preemptive context, which is given by the smallest positive integer $l$ satisfying the following equation

$$l = \max_{j>i} \{ C_j - 1 \} + \sum_{j<i} \left\lfloor \frac{l}{T_j} \right\rfloor C_j.$$

The worst-case response times of the tasks of $T_1$ as determined by this analysis are also included in Table 1. In order to make the analysis applicable, we first multiplied all task parameters with 10, subsequently performed the analysis, and finally divided the resulting worst-case response times by 10. Based on Lemma 1, we conclude that the worst-case response times of tasks $\tau_1$ and $\tau_2$ are illustrated in Figure 2, and of task $\tau_3$ in Figure 1.

5 Conclusion

In this document, we revisited basic worst-case message response times for ideal controller area network (CAN). We showed by means of examples with a high load ($\approx 98\%$) that the analysis as presented in [10] is optimistic. Assuming discrete scheduling, the problem can be resolved by applying the analysis for FPNS presented in [4].

Worst-case response time analysis under FPNS with arbitrary phasing for continuous scheduling is a topic of future work.
