(Received 8 October 2007; published 21 February 2008)

Conducting submicron particles are well suited as filler particles in nonconducting polymer matrices to obtain a conducting composite with a low percolation threshold. Going to nanometer-sized filler particles imposes a restriction to the conductivity of the composite, due to the reduction of the density of states involved in the hopping process between the particles, compared to its value within the crystallites. We show how those microscopic parameters that govern the charge-transport processes across many decades of length scales can accurately and consistently be determined by a range of dielectric-spectroscopy techniques from a few hertz to infrared frequencies. The method, which is suited for a variety of systems with restricted geometries, is applied to densely packed 7-nm-sized tin oxide crystalline particles with various degree of antimony doping and the quantitative results unambiguously show the role of the nanocrystal charging energy in limiting the hopping process.

I. INTRODUCTION

Small submicron particles are well suited as fillers in nonconducting polymer matrices to obtain a conducting composite with a percolation threshold (far) below 1%. The low percolation threshold is due to the formation of airy aggregates of conducting particles, in which the particles are grown together by diffusion-limited cluster aggregation, creating a network with a fractal dimension around 1.7.¹⁻³ These airy aggregates can be thought of as conducting spheres forming a three-dimensional percolating network around the expected aggregate filling fraction of 0.16. As a consequence of the fractal structure within the aggregates, the filler fraction of the particles at the percolation point is much lower. Even in case the particles touch, the dc conductivity (σ_{dc}) of these composites at high filling fractions turns out to be orders of magnitude lower than of the bulk material, as was recently illustrated for a particular cross-linked epoxy composite with filler particles of Phthalcon-11,⁴ Co phthalocyanine crystallites of 100 nm size, and explained by purely structural arguments.⁵

When crystalline particles with a diameter of less than 10 nm instead of 100 nm are used, the small size of the particles may impose another important restriction to the maximal possible composite conductivity, which is due to the density of states (DOS) involved in the dc conductivity through the network of particle contacts. Compared to larger crystallites, this DOS can be strongly reduced by the charging energy.⁶⁻⁹

We show how those microscopic parameters, which govern the charge-transport process across many decades of length scales, can accurately and consistently be determined by ac (alternating current) dielectric spectroscopy from a few hertz to infrared frequencies. In particular, we can address the parameters for Mott variable-range hopping, for heterogeneity-induced enhanced ac response, for phonon- or photon-assisted nearest-neighbor hopping, and for the Drude

response of individual nanocrystals. Due to these quantitative results, we can unambiguously determine also the role of the nanocrystal charging energy in limiting the hopping process. We apply the method to antimony-doped tin oxide (ATO) crystallites of 7 nm diameter and to 100 nm sized crystallites of Phthalcon-11. It turns out that in densely packed crystallites of ATO, due to the strong influence of the charging energy on the DOS, σ_{dc} at room temperature is 4 orders of magnitude lower than the dc conductivity extrapolated from the Drude plasma frequency (ω_{pD}) of the crystallites—a result with obvious implications for the design of conducting composites. The dielectric method is well suited for a variety of systems with restricted geometries, as we will illustrate by a short discussion of phase-change materials¹⁰ and granular oxides.¹¹

II. CONDUCTIVITY IN CONDUCTING POLYMER COMPOSITES AND GRANULAR METALS

For randomly placed conducting spheres in an insulating matrix, the relation between σ_{dc} and the fraction ϕ of spheres is known from percolation theory.^{1,12,13} Above the percolation threshold, $\sigma = \sigma_0 |\phi - \phi_c|^t$, where $\phi_c \approx 0.16$ is the percolation threshold, $t \approx 2.0$, and σ_0 is approximately equal to the conductivity of the spheres.^{3,14} When the building blocks of the network are fractal aggregates instead of solid spheres, σ_0 has to be replaced by the aggregate conductivity σ_a and depends on the particle conductivity and, via the nonlinear relation, $\sigma_a / \sigma_p = (\phi_{p,c} / 0.16)^{1+x}$, with $x > 0$, on the real percolation threshold $\phi_{p,c}$ of the particles.⁵ The value of the exponent x is related to the random-walk dimension and the fractal dimension d_f , and is maximally $2(d_f - 1) / (3 - d_f)$. This shows that on purely geometrical grounds for a network with $\phi_{p,c} = 0.0055$ at the highest filling fraction of the aggregates, σ_{dc} will be 3–4 orders of magnitude lower than in the pure filler powder.⁵

As remarked in the Introduction, when nanosized particles are used as fillers, charging energies (and quantum size effects) impose a further important restriction to the maximal possible composite conductivity.^{6,7} This effect can be conveniently studied in densely packed powders of filler material by dielectric spectroscopy.

A. Parameters for the dc conductivity

In the ohmic regime, if there is a non-negligible density of states around the chemical potential and the temperature T is high enough that also the Coulomb interaction can be neglected ($T > T_{\text{crit}}$), σ_{dc} will obey Mott's equation for conduction via variable-range hopping (VRH),¹⁵

$$\sigma_{\text{dc}} \propto \exp[-(T_{0,\text{Mott}}/T)^\nu], \quad (1)$$

with $\nu = 1/4$ and

$$k_B T_{0,\text{Mott}} \approx 20/(g_{\text{hop}} a^3), \quad (2)$$

where a denotes the decay length of the electron density, k_B the Boltzmann constant, and g_{hop} the density of states relevant in the hopping process.¹⁶

For randomly packed spheres of radius R and spacing s , the localization length $\tilde{a}$ will be enlarged^{7-9,17,18} and can be approximated by^{7,17}

$$\tilde{a} = (2R/s)a. \quad (3)$$

In the following, we drop the tilde.

Below T_{crit} , the T dependence of the conductivity will be dominated by a soft Coulomb gap, leading to the so-called Efros-Shklovskii (ES) VRH,¹⁹

$$\sigma_{\text{dc}} \propto \exp[-(T_{0,\text{ES}}/T)^{1/2}]. \quad (4)$$

In the ES VRH model in the dilute limit of a large distance between the particles, $T_{0,\text{ES}}$ is given by

$$T_{0,\text{ES}} = 2.8e^2/(4\pi\epsilon\epsilon_0 a k_B), \quad (5)$$

with e the electron charge, ϵ_0 the vacuum dielectric constant, and ϵ the relative dielectric constant of the medium. T_{crit} is given by $T_{\text{crit}} \sim e^4 a g_{\text{hop}}/[k_B(4\pi\epsilon\epsilon_0)^2]$ and (for $s > R$) the charging energy by $\sim e^2/(4\pi\epsilon\epsilon_0 R)$.

For densely packed small particles, at high temperatures but still in the regime, where Coulomb interactions are important ($T \leq T_{\text{crit}}$), ES VRH behavior will evolve into nearest-neighbor hopping at a temperature T_A . Above T_A , the conduction is thermally activated with an activation energy ΔE_A of the order of the charging energy, and $T_A \sim (\Delta E_A)^2/T_{0,\text{ES}}$.

The experiments of Yu *et al.*^{6,20} on thin films of highly monodispersed semiconducting nanocrystals of CdSe of 6 nm diameter, slightly smaller than the ATO crystallites discussed here, showed good agreement between the theoretical and experimental value of $T_{0,\text{ES}}$, T_{crit} , and T_A .²¹

B. Subterahertz and far-infrared regime

At sufficiently low frequencies, the conductivity will be frequency independent and equal to its dc value because the

inhomogeneities are averaged out by the motion of the charge carriers. The minimal length scale for homogeneity is referred to as L_{hom} ,

$$L_{\text{hom}}^2 = \sigma_{\text{dc}} k_B T / n_{\text{hom}} e^2 (f_{\text{os}}/2D), \quad (6)$$

where n_{hom} is the density of the carriers involved in the hopping process at the border of the homogenous regime, and the onset frequency f_{os} for the frequency dependence of σ is divided by $2D$, with D the dimension of the system.¹⁶

At high enough frequencies, when during half a period of the oscillation of the applied field electrons can hop solely between nearest neighbors, the major contribution to the conductivity will be due to tunneling between localized states at neighboring sites (the pair limit).²² This incoherent process can be either by phonon-assisted or photon-assisted hopping, where in the latter case the energy difference between the sites is supplied by photons instead of phonons.¹⁶ The phonon-assisted contribution to the conductivity is given by

$$\sigma_{\text{phonon}}(\omega) = \frac{\pi^2}{192} e^2 \omega k_B T L_{\text{hop}}^5 g_{\text{hop}}^2 \ln^4\left(\frac{\omega_{\text{ph}}}{\omega}\right), \quad (7)$$

with $L_{\text{hop}} \sim a$ the decay length of the electronic state outside the conducting particles, g_{hop} the relevant DOS at the Fermi energy E_F , and ω_{ph} the phonon "attempt" frequency.¹⁶ This formula is valid when $\omega < \omega_{\text{ph}}$; at higher ω , where the contribution of phonon-assisted hopping to σ becomes constant, photon-assisted processes usually take over, with a conductivity σ_{photon} given by

$$\sigma_{\text{photon}}(\omega) = \frac{\pi^2}{6} e^2 \hbar \omega^2 L_{\text{hop}}^5 g_{\text{hop}}^2 \ln^4\left(\frac{2I_0}{\hbar \omega}\right). \quad (8)$$

The energy $k_B T$ in Eq. (7) is in Eq. (8) replaced by $\hbar \omega$ and the phonon attempt frequency ω_{ph} by $2I_0$, with I_0 being the "overlap" prefactor for the energy levels of two neighboring sites. In analogy with ω_{ph} , $I_0/\hbar$ can be interpreted as the attempt frequency for photon-assisted hopping. Equation (8) is only valid when $\omega < I_0/\hbar$. As in phonon-assisted hopping, σ passes over into a plateau at high ω .

C. Visible and optical response

At high frequencies (for ATO in the infrared regime), the short period of the electromagnetic field will restrict the motion of the carriers to the nanocrystallite, and the dielectric response characterized by the complex relative dielectric constant $\epsilon(\omega) = 1 - \omega_{\text{pD}}^2/[\omega(\omega + i\Gamma)]$ will be Drude-like, with ω_{pD} the Drude plasma resonance frequency and $\Gamma = 1/\tau$ the damping rate. In practice, the constant 1 has to be replaced by ϵ_∞ due to other contributions in this frequency regime, such as the polarization of the ion cores.²³ The Drude plasma frequency is related to the number of carriers per unit of volume n_{crys} and the effective mass m_e^* as

$$\omega_{\text{pD}}^2 = n_{\text{crys}} e^2 / \epsilon_0 m_e^*. \quad (9)$$

For damping rates comparable to the Drude plasma frequency, the real plasma frequency (where the dielectric constant becomes zero) will be larger than ω_{pD} . Γ is determined by the boundaries of the nanoparticle and additional (ionized impurity) scattering,

FIG. 1. dc conductivity as a function of T for a densely packed powder of 7%-doped ATO. (a) For $T \leq 50$ K, the data can be fitted by Eq. (4), while (b) for $T \geq 50$ K, the T dependence is activated.

$$\Gamma = 1/\tau = v_F/L_{\text{cryst}}, \quad (10)$$

where $1/L_{\text{cryst}}$ is the sum of the inverse size of the particle and the inverse phonon scattering length.

III. EXPERIMENTAL PROCEDURES AND DATA

Measurements were performed on Sb-doped tin oxide nanoparticles with $[\text{Sb}]/([\text{Sn}]+[\text{Sb}])$ equal to 0, 2, 5, 7, 9, and 13 at. %. The particles are monocrystalline and spherical with diameters close to 7 nm.²⁴ The diameter of the 7% doped crystallite is 7.1 nm. Sb is incorporated in the cassiterite SnO_2 lattice by replacing Sn^{4+} . At the doping level of 7%, Sb is mainly present as Sb^{5+} , resulting in n -type conductivity of the ATO particles according to Nütz *et al.*²⁵ The amount of Sb^{3+} present in the particles is negligibly small.^{24,26}

The followed experimental procedures for the dc conductivity and dielectric measurements are described in Refs. 5 and 27. The thickness of the samples was typically a few millimeters. The dc conductivity measurements were performed in the dark under helium atmosphere.

The T dependence is given in Fig. 1, and the frequency dependence at temperatures down to 7 K in Fig. 2. All data shown are for 7%-doped ATO. Similar results were obtained at other doping levels, be it with different absolute values. The data were taken in the Ohmic regime.

The infrared (IR) transmittance was measured on a pellet of KBr mixed with a small amount of ATO. For the IR reflectance, we used a precipitated film of ATO with a thickness of about 1 nm. The data are shown in Fig. 3. For the analysis, we also used the subterahertz transmittance and phase data (only shown in Fig. 4).

In Table I, we summarize our data on densely packed 7 nm sized ATO crystallites and compare them with measurements on doped tin oxide published in the literature. The values of ω_{pD} agree within a factor 2, while the spread in the scattering rates is larger.

FIG. 2. Frequency dependence of the conductivity for 7%-doped ATO at various temperatures. In this double logarithmic plot, the linear dependence at low temperatures is in agreement with Eq. (7).

IV. ANALYSIS AND DISCUSSION

In the analysis, we first show the procedure to extract the parameter values from the data in the different frequency regimes and to check their consistency. We also make a comparison to the parameter values of Phthalcon-11, for which the data are published elsewhere.²⁷ Then, we concentrate on the density of states; the latter being important for the dc conductivity. Subsequently, the implications for the use of the particles as fillers in nanocomposites are discussed.

A. Procedure

Regarding the T dependence of σ (Fig. 1), the data can be fitted with $\nu=1$ [Eq. (1)] if the fit is restricted to $T \geq 50$ K

FIG. 3. Transmittance and reflectance of ATO with 7% Sb doping in the infrared, after background correction. (a) For the transmission ATO is mixed with KBr and pressed into a 0.57 mm thick pellet to have sufficient transparency. The oscillations in the fit to the transmittance are an artifact (the fit is based on the calculated effective ATO-film thickness of 0.005 mm). (b) Like for the subterahertz data, the reflection data are taken from precipitated films of 1 nm thick typically. The Drude fit is discussed in the text. The data compare well with the data published in the literature (see Table I).

FIG. 4. The various contributions to the conductivity as function of photon energy. At room temperature at the lowest frequencies the conductivity is dominated by charging energies, at intermediate frequencies phonon and photon assisted hopping processes describe the frequency dependence, and in the infrared the Drude conductivity inside the crystallites is seen.

and with $\nu=0.5$ [Eq. (4)] for $T \leq 50$ K. The $\nu=1$ fit gives an activation energy of 10^2 K, while the exponent $\nu=0.5$ at low T gives $T_{0,ES}=0.6 \times 10^4$ K. The localization length from $T_{0,ES}$ [see Eq. (5)] is calculated to be $a=3$ nm. Using Eq. (3) and $(2R/s)=10$ estimated from the packing density, we find $a \sim 2$ nm, in good agreement with the value calculated from $T_{0,ES}$.

The onset of the frequency dependence of the conductivity (see Fig. 2) signals that the carrier starts to feel the inhomogeneity of the underlying structure. Using Eq. (7), the typical length scale L_{hom} at the onset can be found. For 7%-doped ATO at 300 K, the onset frequency $f_{os}=3 \times 10^8$ Hz and $\sigma_{dc}=10^{-2}$ S/cm give a value of $L_{hom}^2 n_{hom}=9 \times 10^7$ cm $^{-1}$.

The linear frequency dependence of the conductivity at 7 K in the double logarithmic plot of Fig. 2 is in agreement with phonon-assisted tunneling [see Eq. (7)]. In the range of 10 – 100 cm $^{-1}$, photon-assisted processes take over.³⁰ Applying Eq. (7) to the conductivity data at 293 K and taking the usual value for the phonon frequency in solids $\omega_{ph}=10^{12}$ s $^{-1}$,^{16,30} we find $L_{hop}^5 g_{hop}^2=3 \times 10^3$ eV $^{-2}$ cm $^{-1}$ (see Fig. 4).

Turning next to the high-frequency data presented in Fig. 3, we performed a simple Drude analysis. The fit (ω_{pD}

$=11\,000$ cm $^{-1}$ and $\tau=3300$ cm $^{-1}$, together with a dielectric constant of 4.0) reproduces the main features of the increase of the transmission and the level of the reflectance (the oscillations in the fit to the transmittance are an artifact because the effective ATO film thickness of 0.005 mm is much smaller than the real thickness of the pressed KBr pellet). The number of carriers n_{crys} of 10^{21} cm $^{-3}$ is directly derived from the Drude frequency and is slightly lower than obtained from a simple interpretation of the chemical composition. The bulk dc conductivity calculated from the Drude parameters is 10^2 S/cm. The fit parameters of the present samples are given in Table I and agree well with the literature.

Figure 4 shows the reconstructed conductivity of ATO as function of frequency due to the processes discussed above. For ATO, the important values for the dc conductivity can be deduced from the combination of variables that we found from the previous analysis: (i) $L_{hom}^2 n_{hom}=9 \times 10^7$ cm $^{-1}$, (ii) $g_{hop}^2 L_{hop}^5=8 \times 10^{43}$ J $^{-2}$ m $^{-1}$ or 3×10^3 eV $^{-2}$ cm $^{-1}$ for photon-assisted hopping and 10^{42} J $^{-2}$ m $^{-1}$ for the phonon fit to the data at 7 K, and (iii) $n_{crys}=10^{21}$ cm $^{-3}$ and $\tau=10^{-14}$ s.

Using (iii) the “extrapolated” dc conductivity is 10^2 S/cm, a factor 10^4 larger than the found value of 10^{-2} S/cm. The estimated Fermi energy E_F is around 2 eV and from $g(E)=(3/2)(n/E_F)$ (valid for free electrons), we get $g(E_F)=5 \times 10^{21}$ eV $^{-1}$ cm $^{-3}$. From (ii), with $L_{hop}=a$ of 3 nm, we find for $g_{hop}=3 \times 10^{18}$ eV $^{-1}$ cm $^{-3}$, a factor 10^3 lower than $g(E_F)$. Note that this is an averaged density of states involved in photon-assisted hopping. Due to the curvature of the density of states around the chemical potential, $g(E)$ will be lower at lower energies. For example, for the phonon fit at 7 K g_{hop} is equal to 0.3×10^{18} eV $^{-1}$ cm $^{-3}$.

The values for τ and L_{hom} can be used as a consistency check. The combination of the estimated Fermi velocity of 0.8×10^8 cm/s, with the crystallite size of 7 nm and $m_e^*=0.3m_e$,²⁵ predicts a surface scattering rate of 10^{14} s $^{-1}$, in agreement with the found value of Γ . Next, from $g_{hop} k_B T \sim n_{hom}$ eV $^{-1}$ cm $^{-3}$, we now can estimate n_{hom} at $T=293$ K as $n_{hom}=10^{17}$ cm $^{-3}$. Using (i) and n_{hom} , we find $L_{hom}=0.3$ μ m.

In short, the dielectric data of ATO allow a consistent picture of the conduction process. In these densely packed crystallites, the localization length is enhanced by a factor 10 and the density of states involved in the dc conductivity is more than a factor 10^3 smaller than that in the conduction

TABLE I. Transport parameters obtained for ATO and indium tin oxide (ITO) (second row) at doping levels of 10^{20} – 10^{21} /cm 3 . The room-temperature dc conductivities are given in S/cm, the Drude frequencies and damping rate in s $^{-1}$, and the effective mass in free-electron masses. The first and second rows are obtained for films of ATO (Ref. 28) and ITO (Ref. 29), respectively, and the last two rows contain the data on powders of 6% doped ATO particles of Nütz *et al.* (Ref. 25) and our data (labeled as pw for present work) on samples with 7% Sb doping. For a bulk material with a Drude frequency of 10^{15} Hz, a scattering time of 10^{-14} s, and a carrier mass of $0.3m_e$, a dc conductivity is expected of 10^2 S/cm.

Sample	N (cm $^{-3}$)	σ_{dc} (S/cm)	ω_{pD} (s $^{-1}$)	Γ (s $^{-1}$)	m_e^* (m_e)
ATO film	2×10^{20}	10^2	10^{15}	8×10^{14}	0.3
ITO film	10^{21}		5×10^{14}	3×10^{14}	0.35
ATO powder	2×10^{21}	10^{-6}	10^{15}	6×10^{14}	0.27
ATO powder (pw)	10^{21}	10^{-2}	4×10^{14}	10^{14}	0.3

within the crystallites. The relatively large length scale for homogeneity is indicative for the presence of aggregates. Indeed, like in Ketjen-Black,² nanoparticles of ATO are known to form chemically bonded aggregates that survive the preparation stage.²⁴ Due to the nature of the chemical bond, the conductivities between neighboring crystallites in and outside the aggregates are expected to be only slightly different. Note that also the value of g_{crys} has to be seen as an average, as inhomogeneities in the doping of ATO might be present as well.^{26,24}

For the studied Phthalcon-11 crystallites, $\omega_{\text{pD}}=10^{13} \text{ s}^{-1}$ and $\tau=10^{-13} \text{ s}$ leading to $n_{\text{crys}}=2 \times 10^{15} \text{ cm}^{-3}$, i.e., about one charge per crystallite.²⁷ The other values found for Phthalcon-11 are (i) $L_{\text{hom}}^2 n_{\text{hom}}=2 \times 10^6 \text{ cm}^{-1}$ and (ii) $g_{\text{hop}}^2 L_{\text{hop}}^5=10^{43} \text{ J}^{-2} \text{ m}^{-1}$ or $2.5 \times 10^3 \text{ eV}^{-2} \text{ cm}^{-1}$. In these organic crystals with such a low carrier density, the charge carriers can be seen as an electron gas with an energy scale set by $k_B T$, and $g(E)$ can be estimated from $g(E)k_B T \sim n_{\text{crys}}$ to be $10^{17} \text{ eV}^{-1} \text{ cm}^{-3}$. This value of $g(E)$ is the upper limit for g_{hop} and g_{hom} . From $g_{\text{hom}}=10^{17} \text{ eV}^{-1} \text{ cm}^{-3}$, we find a decay length a of 3 nm, as expected from the packing.

The Phthalcon-11 parameters show that the crystals are semiconducting crystals with a low number of charge carriers. All charges participating in the conductivity within the crystal also contribute to the dc conductivity. As for ATO, the obtained conduction parameters for Phthalcon-11 from the dielectric scans give a consistent picture.

B. Density of states

For ATO, the differences between the density of states involved in the hopping process $g_{\text{hop}}=3 \times 10^{18} \text{ eV}^{-1} \text{ cm}^{-3}$ and the Drude conduction within the crystallites $g(E_F)=5 \times 10^{21} \text{ eV}^{-1} \text{ cm}^{-3}$ are clearly significant. The result is as anticipated from the estimated charging energy of the order of 50 meV and shows its importance for the dc powder conductivity.

For Phthalcon-11, the very low number of carriers involved in the hopping process is similar to the number of carriers that determines the Drude contribution in the crystallites. Since the mean size of the particles is 20 times larger than for ATO, the charging energies will be of the order of 3 meV, and hence are expected to be negligible at room temperature.

C. Implications

In polymer nanocomposites with building blocks formed by diffusion-limited cluster aggregation, the fractal structure of the particle network gives a strong reduction in conductivity of the composite compared to the filler (for the Phthalcon11/polymer composite, a factor of 10^4).⁵ This effect can be compensated by using better conducting particles. Particles of ATO or ITO seem to be well suited as the material is known to be very well conducting. In addition, ATO crystallites are relatively easily obtained in sizes around 7 nm, and when properly dispersed can give polymer com-

posites with a low percolation threshold.³¹ However, even if the filler nanoparticles in the composite touch, they will not be in better contact than in a densely packed powder. As shown here for ATO, for these small crystallites, the DOS involved in σ_{dc} is dramatically reduced due to the shift of the energy levels away from the Fermi level by Coulomb charging effects. As a consequence, an additional 4 orders of magnitude in σ_{dc} are lost compared to the bulk value.

Other systems where size restrictions are expected to be present might be conveniently studied in a similar way. For example, several chalcogenide alloys exhibit a pronounced contrast between the optical absorption in the metastable rocksalt after the intense laser pulse and in the initial amorphous phase.¹⁰ As shown by extended x-ray absorption fine structure spectroscopy, the resistive change after the intense laser recording pulse goes together with a crystallization process, where also small domains are inherently present. Our dielectric method might visualize to what extent the domain walls after crystallization limit the conductivity and have consequences for the band structure calculations. If the walls become real barriers, quantum size effects in the small domains will invalidate the use of periodic boundary conditions in the calculations. Also, the glassy behavior in the conductance of deposited indium tin oxide samples in the insulating regime¹¹ and of quench-condensed insulating granular metals³² might be further clarified by the use of our dielectric approach and analysis. Scanning the frequency will reveal the evolution of the length scales and DOS involved in the relaxation processes.

V. CONCLUSIONS

By combining data of subterahertz transmission with infrared transmission and reflection, we were able to explain the full frequency response of densely packed nanosized crystallites using the parameters for Mott variable-range hopping, for heterogeneity-induced enhanced ac response, for phonon- or photon-assisted nearest-neighbor hopping, and for the Drude response of individual nanocrystals. For 7 nm antimony-doped tin oxide particles, the analysis unambiguously quantified the reduction of the density of states involved in the dc conduction compared to the value extrapolated from the Drude response at infrared frequencies. Dielectric scans with a similar analysis will also be revealing in other systems where size limitations are expected to play a role.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge Roel van de Belt of Nano Specials (Geleen, The Netherlands), who made the ATO samples available, and Matthias Wuttig from the Physikalisches Institut of the RWTH Aachen University in Germany for fruitful discussions about phase-change materials. This work forms part of the research program of the Dutch Polymer Institute (DPI), project DPI435.
