Abstract: We consider the critical survival probability (up to time $t$) for oriented percolation and the contact process, and the point-to-surface (of the ball of radius $t$) connectivity for critical percolation. Let $\theta_t$ denote both quantities. We prove in a unified fashion that, if $\theta_t$ exhibits a power law and both the two-point function and its certain restricted version exhibit the same mean-field behavior, then $\theta_t \simeq t^{-1}$ for the time-oriented models with $d > 4$ and $\theta_t \simeq t^{-2}$ for percolation with $d > 7$.

Keywords: Percolation; oriented percolation; the contact process; survival probability; point-to-surface connectivity; critical exponents; mean-field behavior.
AMS Subject Classification: 60K35; 82B43; 82C22.
1 Introduction

Percolation, oriented percolation and the contact process are known to exhibit a phase transition. Various interesting properties around the model-dependent critical point $p_c$ have been studied and revealed, but still there are many open problems. One of the most important problems is to investigate critical exponents that characterize singular behavior of observables. Some of them were identified in certain situations.

In this paper, we consider the critical survival probability up to time $t$ for oriented percolation and the contact process, and the probability of the origin $o \in \mathbb{Z}^d$ being connected to the surface of the ball of radius $t$, centered at the origin, for critical percolation. Since the survival probability is a time-oriented version of the point-to-surface connectivity, we denote both quantities by $\theta_t$. It is believed that $\theta_t$ exhibits a power law: $\theta_t \approx t^{-1/\delta_r}$ as $t \to \infty$ (in some appropriate sense). In the percolation school, $\delta_r$ is sometimes called the one-arm exponent.

Lawler, Schramm and Werner proved $\delta_r = 48/5$ for the two-dimensional site percolation on the triangular lattice, using the estimates for the stochastic Loewner evolution with parameter 6 (see [21] for a precise statement). Except for this result, there has been no proof of existence of $\delta_r$, or identification of its values for finite-range models in mathematically rigorous manner, even in high dimensions.

In contrast, the behavior of the two-point function is well-understood in high dimensions. For percolation, the two-point function at $p_c$, denoted $\tau(x)$, is the probability of $o, x \in \mathbb{Z}^d$ being connected to each other, defined at $p_c$. It has been proved that $\tau(x) \asymp |x|^{-(d-\eta)}$ as $|x| \to \infty$ with $\eta = 0$ when $d > 6$ and the number $N$ of neighbors is sufficiently large [9, 10], where “$\asymp$” means that the left-hand side divided by the right-hand side is bounded away from zero and infinity. For the time-oriented models, the two-point function at $p_c$, denoted $\tau_t(x)$, is, in terms of the contact process, the probability of $x \in \mathbb{Z}^d$ being infected at time $t$ by the infected individual at $o \in \mathbb{Z}^d$ at time 0, defined at $p_c$. It has been proved that $\sup_x \tau_t(x) \asymp t^{-d/\alpha}$, $\check{\tau}_t \equiv \sum_x \tau_t(x) \asymp t^n$ and $\sum_x |x|^2 \tau_t(x)/\check{\tau}_t \asymp t^{2\nu}$ as $t \to \infty$, with $\alpha = 2, \eta = 0$ and $\nu = 1/2$, when the spatial dimension $d$ is above 4 and $N$ is sufficiently large [17, 19, 20, 23]. These dimension-independent values of the critical exponents are equal to the values for branching random walk (mean-field model). Let $\rho (= 1/\delta_r)$ be defined by $\theta_t \asymp t^{-\rho}$ as $t \to \infty$. It is not so hard to see that $\eta = 0$ implies $\rho \leq 2$ for percolation and $\rho \leq 1$ for the time-oriented models (see Section 3.1), where the upper bounds are the mean-field values of $\rho$.

On the other hand, the critical exponents are known to satisfy the so-called hyperscaling inequalities, e.g., $d - 2 + \eta \geq 2\rho$ for percolation [27] and $d\nu \geq \eta + 2\rho$ for the time-oriented models [25, (5.2) and (5.4)], where the critical exponents were defined in a wider sense. Other hyperscaling inequalities were also derived in [7, 25, 27]. By those inequalities, the mean-field values are known to be incompatible with $d < 6$ for percolation and with $d < 4$ for the time-oriented models. These threshold dimensions are called the upper critical dimensions for the
corresponding models.

In this paper, we prove in a unified way that $\rho$ takes on the mean-field values for the time-oriented models with $d > 4$ and for percolation with $d > 7$, if $\rho$ exists and both the two-point function and its certain restricted version exhibit the same mean-field behavior (see Assumption 2.1). The assumption on the restricted two-point function is expected to hold above the upper critical dimension for each model, but is still insufficient to extend $\rho = 2$ for percolation down to $d > 6$. For sufficiently spread-out oriented percolation with $d > 4$, the asymptotic behavior of $\theta_t$ with $\rho = 1$ will be reported in [15, 16], without any assumption on the restricted two-point function. In this respect, our results are not so strong as the results in [15, 16] for oriented percolation. However, the approach reported in this paper is short and intuitive, and more importantly, gives a unified approach for both the time-oriented models and percolation. We expect that, with the help of the random-current representation [1], our unified approach could be applied to the single-spin expectation $\langle \sigma_o \rangle_t$ for Ising ferromagnet in the box of side length $t$ (with plus-boundary condition), and result in the mean-field behavior, i.e., $\langle \sigma_o \rangle_t \asymp t^{-1}$ as $t \to \infty$, at the critical temperature in high dimensions. This will be discussed in [26].

We organize the rest of this paper as follows. In Section 2, we define the models and state the main result. A brief explanation of the proof is given at the end of Section 2, and the detailed proof is given in Section 3.

## 2 Models and the results

### 2.1 Models

We consider the $d$-dimensional integer lattice $\mathbb{Z}^d$ as space. For $L \geq 1$, let

$$
\Omega = \{x \in \mathbb{Z}^d : 0 < |x| \leq L\}, \quad D(x) = N^{-1} \mathbb{1}_{\{x \in \Omega\}}, \quad (2.1)
$$

where $|x|$ is the Euclidean norm of $x$, $N$ is the cardinality of $\Omega$, and $\mathbb{1}_{\{\cdots\}}$ is the indicator function. The model with $L = 1$ is the nearest-neighbor model, where $N = 2d$. We call the model with $L > 1$ the spread-out model, where $N = O(L^d)$ (see, e.g., [17] for a more general definition). Our models are defined in terms of $D$ as follows.

**Percolation.** A bond $\{x, y\}$ is an unordered pair of distinct sites in $\mathbb{Z}^d$, and is occupied with probability $pD(y - x)$ and vacant with probability $1 - pD(y - x)$, independently of the other bonds, where $p \in [0, N]$ is the expected number of occupied bonds growing out of a single site. We denote by $\mathbb{P}_p$ the probability distribution for the bond variables. We say that $x$ is connected to $y$, and write $x \leftrightarrow y$, if either $x = y$ or there is a path of occupied bonds between $x$ and $y$. We define $C(x) = \{y \in \mathbb{Z}^d : x \leftrightarrow y\}$. For $\mathcal{Z} \subset \mathbb{Z}^d$, we write $\{x \leftrightarrow \mathcal{Z}\} = \{C(x) \cap \mathcal{Z} \neq \emptyset\}$. 2
It is known that there is a critical value \( p_c = p_c(d, L) \geq 1 \) such that \( \sum_x P_p(o \leftrightarrow x) \) is finite if and only if \( p < p_c \) and diverges as \( p \uparrow p_c \). Let
\[
B_t = \{ x \in \mathbb{Z}^d : |x| \leq t \}, \quad \partial B_t = \{ x \in \mathbb{Z}^d : t \leq |x| \leq t + L \}.
\] and define the two-point function and the point-to-surface connectivity at \( p_c \) as
\[
\tau(x) = P_{p_c}(o \leftrightarrow x), \quad \theta_t = P_{p_c}(o \leftrightarrow \partial B_t).
\]
We are interested in the critical exponents \( \eta \) and \( \rho \), defined by
\[
\tau(x) \asymp \|x\|^{-(d-2+\eta)}, \quad \theta_t \asymp \|t\|^{-\rho},
\]
where \( f \asymp g \) means that \( f/g \) is bounded away from zero and infinity, and where \( \| \cdot \| = | \cdot | \vee 1 \). Note that \( \| \cdot \| \) is not a norm on \( \mathbb{R}^d \), but it satisfies the following properties: for \( x, y \in \mathbb{R}^d \) and \( r > 0 \),
\[
\|x + y\| \leq \|x\| + \|y\|, \quad \|rx\| \begin{cases} \leq r\|x\|, & \text{if } r \geq 1, \\ \geq r\|x\|, & \text{if } r < 1. \end{cases}
\]
We also note that the above definition of \( \rho \) is based on the assumption that \( \theta_t \) decays as \( t \to \infty \). This has been confirmed only when \( d = 2 \) or \( d \geq 19 \) with \( L = 1 \), and \( d > 6 \) with \( L \gg 1 \) (see, e.g., \[8, 12\]).

It has been proved that \( \eta = 0 \) for the nearest-neighbor model with \( d \gg 6 \) \[9\] and for the spread-out model with \( d > 6 \) and \( L \gg 1 \) \[10\]. The critical exponent \( \eta \) is believed to be independent of the range \( L \), as long as it is finite (universality), and thus is expected to be zero for all \( d > 6 \) and \( L \geq 1 \). This dimension-independent value of \( \eta \) equals the corresponding value for the mean-field model. Various other critical exponents are also known to take on their respective mean-field values, if (see \[3\] and references therein)
\[
\nabla_\ell \equiv \sup_{x \in B_\ell} (\tau \ast D \ast \tau \ast \tau)(x) \to 0, \quad \text{as } \ell \to \infty,
\]
where “\( \ast \)” represents a convolution in \( \mathbb{Z}^d \). With the help of \[10, Proposition 1.7(i)\], \( \eta = 0 \) implies \( \nabla_\ell = O(\ell^{-(d-6)}) \) if \( d > 6 \), and thus implies the mean-field values for all the other critical exponents, except for \( \rho \) until now.

Oriented percolation and the contact process. We begin with oriented percolation. A bond \( ((x, t), (y, t+1)) \) is an ordered pair of sites in \( \mathbb{Z}^d \times \mathbb{Z}_+ \), and is occupied with probability \( p D(y-x) \) and vacant with probability \( 1 - p D(y-x) \), independently of the other bonds, where \( p \in [0, N] \). We say that \( (x, s) \) is connected to \( (y, t) \), and write \( (x, s) \to (y, t) \), if either \( (x, s) = (y, t) \) or there is an oriented path of occupied bonds from \( (x, s) \) to \( (y, t) \). Let \( C(x, s) = \{ (y, t) \in \mathbb{Z}^d \times \mathbb{Z}_+ : (x, s) \to (y, t) \} \). For \( Z \subset \mathbb{Z}^d \times \mathbb{Z}_+ \), we define \( \{ (x, s) \to Z \} = \{ C(x, s) \cap Z \neq \emptyset \} \).
The contact process is a model for the spread of an infection in $\mathbb{Z}^d$, and is regarded as continuous-time oriented percolation in $\mathbb{Z}^d \times \mathbb{R}_+$, via the following graphical representation. Along each time line $\{x\} \times \mathbb{R}_+$, we place points in the manner of a Poisson process with intensity 1, independently of the other time lines. For each ordered pair of distinct time lines from $\{x\} \times \mathbb{R}_+$ to $\{y\} \times \mathbb{R}_+$, we place oriented bonds $((x, t), (y, t))$, $t \geq 0$, in the manner of a Poisson process with intensity $p D(y-x)$, independently of the other Poisson processes, where $p \geq 0$ is the infection rate. We say that $(x, s)$ is connected to $(y, t)$, and write $(x, s) \rightarrow (y, t)$, if either $(x, s) = (y, t)$ or there is an oriented path in $\mathbb{Z}^d \times \mathbb{R}_+$ from $(x, s)$ to $(y, t)$ using the Poisson bonds and time-line segments traversed in the increasing-time direction without traversing the Poisson points. We define $C(x, s)$ and $\{ (x, s) \rightarrow Z \}$ for $Z \subset \mathbb{Z}^d \times \mathbb{R}_+$ similarly to oriented percolation.

We denote by $\mathbb{P}_p$ the probability distributions for these time-oriented models. It is known that there is a critical value $p_c = p_c(d, L) \geq 1$, depending on the models, such that the sum over $t \in \mathbb{Z}_+$ of $\sum_x \mathbb{P}_p((o, 0) \rightarrow (x, t))$ for oriented percolation, or the integral of $\sum_x \mathbb{P}_p((o, 0) \rightarrow (x, t))$ with respect to $t \in \mathbb{R}_+$ for the contact process, is finite if and only if $p < p_c$ and diverges as $p \uparrow p_c$. Let

$$B_t = \mathbb{Z}^d \times [0, t], \quad \partial B_t = \mathbb{Z}^d \times \{t\},$$

and define the two-point function and the survival probability at $p_c$ as

$$\tau_t(x) = \mathbb{P}_{p_c}((o, 0) \rightarrow (x, t)), \quad \theta_t = \mathbb{P}_{p_c}((o, 0) \rightarrow \partial B_t).$$

We are interested in the critical exponents $\alpha, \eta, \nu$ and $\rho$, defined by

$$\bar{\tau}_t \equiv \sup_{x \in \mathbb{Z}^d} \tau_t(x) \asymp \|t\|^{-d/\alpha}, \quad \hat{\tau}_t \equiv \sum_{x \in \mathbb{Z}^d} \tau_t(x) \asymp \|t\|^\eta,$$

$$\sum_{x \in \mathbb{Z}^d} |x|^2 \frac{\tau_t(x)}{\tau_t} \asymp \|t\|^{2\nu}, \quad \theta_t \asymp \|t\|^{-\rho},$$

where, by analogy, we used the same letters $\eta$ and $\rho$ for the critical exponents of the spatial sum of the two-point function and the survival probability, respectively.

It has been proved that $(\alpha, \eta, \nu) = (2, 0, \frac{1}{2})$ for the time-oriented models with $d > 4$ and $L \gg 1$ [17, 20]. The same result except for $\alpha = 2$ was proved in [23] for nearest-neighbor oriented percolation with $d \gg 4$, but there have been no results on this set of exponents for the nearest-neighbor contact process. Other critical exponents for both the nearest-neighbor and spread-out time-oriented models are known to take on their respective mean-field values, if (see [4] and references therein)

$$\nabla_{\ell} \equiv \sup_{x: |x| \geq \ell, t \geq 0} \nabla (x, t) \rightarrow 0, \quad \text{as} \quad \ell \rightarrow \infty,$$

$$4$$
where, for oriented percolation,
\[
\nabla(x, t) = \sum_{s, s' \in \mathbb{Z}_+^d: t \leq s' \leq s} \tau_{s+1}(y) \left( \tau_{s'-t} \ast D \ast \tau_{s-s'}(y-x) \right),
\] (2.12)

and for the contact process,
\[
\nabla(x, t) = \int_t^\infty ds \int_s^t ds' \sum_{y \in \mathbb{Z}^d} \tau_s(y) \left( \tau_{s'-t} \ast D \ast \tau_{s-s'}(y-x) \right). \tag{2.13}
\]

Since the range of the set of infected sites almost surely grows at most linearly [5], \((\alpha, \eta) = (2, 0)\) implies \(\nabla_\ell = O(\|\ell\|^{-(d-4)/2})\) if \(d > 4\), and thus implies the mean-field values for all the other critical exponents than \(\rho\).

### 2.2 Results

In this paper, we prove in a unified fashion for all three models that the mean-field behavior for the two-point function implies the mean-field values of \(\rho\), assuming existence of \(\rho\) and the following assumption.

**Assumption 2.1.** There are positive constants \(C_1 = C_1(d, L)\) and \(C_2 = C_2(d, L)\) that are independent of \(t\) such that, for the time-oriented models,
\[
\sum_{(x, s) \in \mathcal{B}_{t/2}} \mathbb{P}_{p_c}((0, 0) \rightarrow (x, s), (0, 0) \not\in \partial \mathcal{B}_t) \geq C_1 \|\ell\|, \tag{2.14}
\]

and for percolation,
\[
\sum_{x \in \mathcal{B}_{t/2+L}} \mathbb{P}_{p_c}(x \leftrightarrow (0, 0), x \not\in \partial \mathcal{B}_t) \geq C_2 \|\ell\|^2, \tag{2.15}
\]

where \(\mathcal{B}_{t/2+L} = \mathcal{B}_{t/2} \cup \partial \mathcal{B}_{t/2}\).

The unrestricted two-point functions defined in (2.3) and (2.8), with \(\eta = 0\), satisfy the above inequalities. Therefore, Assumption 2.1 states, in a weak sense, that the above restricted two-point functions exhibit the same mean-field behavior as the unrestricted two-point functions.

**Theorem 2.2.** Suppose that \(\eta = 0\) and \(\alpha = 2\) (the latter is only for the time-oriented models). If \(\rho\) exists and Assumption 2.1 holds, then \(\rho = 1\) for the time-oriented models with \(d > 4\) and \(\rho = 2\) for percolation with \(d > 7\).
We briefly explain the main idea of the proof. It is easy to show that $\eta = 0$ implies $\rho \leq 1$ for the time-oriented models and $\rho \leq 2$ for percolation (see Section 3.1). It thus suffices to prove the opposite inequalities for $\rho$. Let us consider typical configurations for $\theta_t$. When $t \gg 1$, there may be a pivotal bond for the connection from the origin to the boundary $\partial B_t$. We take notice of the last pivotal bond $b$, where we have a connection from the origin to the first endpoint of $b$ and two disjoint connections from the second endpoint of $b$ to $\partial B_t$ (see Figure 1). If we could bound the probability of these configurations from below by $\theta_t^2$ times the sum of the unrestricted two-point function (over $b = (\bar{b}, \tilde{b})$ with $\tilde{b} \in B_{t/2}$, as in Figure 1), then $\eta = 0$ implies

$$t^{-\rho} \geq \begin{cases} ct^{1-2\rho}, & \text{for the time-oriented models,} \\ ct^{2-2\rho}, & \text{for percolation,} \end{cases} \quad (2.16)$$

for some positive constant $c$, and thus $\rho \geq 1$ for the time-oriented models and $\rho \geq 2$ for percolation.

To realize the above idea, we have to control the correction. As we will show in Section 3.2, most error terms can be made small by letting $\nabla \ll 1$ and $t \gg 1$ in high dimensions. However, the correction due to the above approximation using the unrestricted two-point function cannot be controlled by a finite number of applications of the BK inequality (see, e.g., [6, 8]), and here we will use Assumption 2.1. The desired asymptotic behavior of $\theta_t$ for spread-out oriented percolation with $d > 4$ and $L \gg 1$ will be reported in [15, 16], with no assumption on the restricted two-point function. The proof in [15, 16] is based on the lace expansion for $\theta_t$, and the difference between the restricted and unrestricted two-point functions is efficiently taken into account along the expansion. Our proof of Theorem 2.2 does not depend on the full expansion as in [15, 16], and Assumption 2.1 is inevitable.
We remark that Assumption 2.1 is still insufficient to fully control the boundary effect and thus to obtain $\rho = 2$ for percolation with $d > 6$. To improve the result down to $d > 6$, we may also need some information on the restricted two-point function close to the boundary (see Remark at the end of Section 3.2).

3 Proofs

We prove Theorem 2.2 in two steps. First, in Section 3.1, we prove that $\eta = 0$ implies $\rho \leq 1$ for the time-oriented models and $\rho \leq 2$ for percolation. Then, in Section 3.2, we prove that $\eta = 0$ and $\alpha = 2$ (the latter is only for the time-oriented models) imply the opposite inequalities for $\rho$, if $d > 4$ for the time-oriented models and $d > 7$ for percolation, assuming existence of $\rho$ and Assumption 2.1.

In the rest of this paper, we omit the subscript $p_c$ and write $E$ for the expectation with respect to $P = \mathbb{P}_{p_c}$. We will use $c$ to denote a finite positive constant which may depend on $d$ and $L$, but whose exact value is unimportant and may change from line to line.

3.1 Proof of the upper bound

Proof for the time-oriented models. Let

$$I_t = \mathbb{1}_{\{(o,0)\rightarrow \partial \mathcal{B}_t\}}, \quad X_t = \sum_{x \in \mathbb{Z}^d} \mathbb{1}_{\{(o,0)\rightarrow (x,t)\}},$$

so that $E(I_t) = \theta_t$ and $E(X_t) = \hat{\tau}_t$. By the Schwarz inequality, we obtain

$$\hat{\tau}_t^2 = E(I_t X_t^2) \leq E(I_t^2) E(X_t^2) = \theta_t \sum_{x,y} \mathbb{P}_{p_c}((o,0) \rightarrow (x,t), (o,0) \rightarrow (y,t)).$$

If $(o,0) \rightarrow (x,t)$ and $(o,0) \rightarrow (y,t)$ occur simultaneously, then there exists a $(z,s) \in \mathcal{B}_t$ such that $(o,0) \rightarrow (z,s)$ occurs and that $(z,s) \rightarrow (x,t)$ and $(z,s) \rightarrow (y,t)$ occur disjointly, i.e., on disjoint sets of bonds. Using the Markov property, the BK inequality and $\eta = 0$, we can bound the sum in (3.2) by

$$\int_0^t ds \sum_{x,y,z \in \mathbb{Z}^d} \tau_s(z) \tau_{t-s}(x-z) \tau_{t-s}(y-z) = \int_0^t ds \ \hat{\tau}_s \ \hat{\tau}_{t-s}^2 \leq c \|t\|.$$

(The integral is replaced by $\sum_{s=0}^t$ for oriented percolation.) Together with (3.2), we thus obtain $\rho \leq 1$, if $\rho$ exists. \qed
Remark. For spread-out oriented percolation with $d > 4$ and $L \gg 1$, Theorem 4.1 and Lemma 4.2 in [14] imply that the left-hand side of (3.2) is asymptotically $A^2$, while the sum in the right-hand side of (3.2) is asymptotically $A^3 V t$, where $A$ and $V$ are constants depending only on $d$ and $L$. This leads to a lower bound on $\theta_t$ like $(AVt)^{-1}$, which is consistent with [14, Theorem 1.5], where the limit $\lim_{t \to \infty} t \theta_t$, if it exists, equals $2(AV)^{-1}$.

**Proof for percolation.** We follow the same strategy as above. Let

$$I_t = 1_{\{o \to \partial B_t\}}, \quad \quad X_t = \sum_{x \in \partial B_t} 1_{\{o \to x\}}.$$ (3.4)

Using the Schwarz inequality as in (3.2), we obtain

$$\left[ \sum_{x \in \partial B_t} \tau(x) \right]^2 = \mathbb{E}(I_t X_t)^2 \leq \mathbb{E}(I_t^2) \mathbb{E}(X_t^2) = \theta_t \sum_{x,y \in \partial B_t} \mathbb{P}_c(o \leftrightarrow x, \quad o \leftrightarrow y).$$ (3.5)

Since $\eta = 0$, the leftmost quantity is bounded from below by $c \|t\|^2$. If $o \leftrightarrow x$ and $o \leftrightarrow y$ occur simultaneously, then there is a $z \in \mathbb{Z}^d$ such that $o \leftrightarrow z$, $z \leftrightarrow x$ and $z \leftrightarrow y$ occur disjointly. By the BK inequality and $\eta = 0$, the sum in the right-hand side of (3.5) is bounded by

$$\sum_{x \in \partial B_t} \tau(z) \tau(x - z) \tau(y - z) = \sum_{x,y \in \partial B_t} \tau(z) \tau(x - z) \tau(y - z) + \sum_{x,y \in \partial B_t, z \notin \partial B_{t/2}} \tau(z) \tau(x - z) \tau(y - z) \leq c\|t\|^{2(2-d)+2(d-1)} \sum_{z \in \partial B_{t/2}} \|z\|^{2-d} + c\|t\|^{2-d} \sum_{x,y \in \partial B_t, z \in \mathbb{Z}^d} \|x - z\|^{2-d} \|y - z\|^{2-d},$$ (3.6)

where we used $|x - z| \geq t/2$ and $|y - z| \geq t/2$ in the first sum, and $|z| \geq t/2$ in the second sum. By [10, Proposition 1.7(i)], the convolution of $\|x - z\|^{2-d}$ and $\|y - z\|^{2-d}$ is bounded by $c \|x - y\|^{4-d}$, whose sum over $x, y \in \partial B_t$ is bounded by $c\|t\|^{2(d-1)+4-d} = c\|t\|^{d+2}$. Therefore, (3.1) is bounded by $c\|t\|^4$, and we obtain $\rho \leq 2$ using (3.5).

### 3.2 Proof of the lower bound

In this section, we will use $\epsilon = \epsilon(\rho)$ defined by

$$\epsilon(\rho) \begin{cases} > 0 \text{ (but arbitrarily small)}, & \text{if } \rho = 1, \\ = 0, & \text{if } \rho \neq 1, \end{cases}$$ (3.7)

for both the time-oriented models and percolation.

**Proof for the time-oriented models.** We only consider oriented percolation, since the same idea given below also applies to the time-discretized contact process in [17, 24] that weakly converges to the original contact process as the discretized-time unit tends to zero. We prove below

$$\theta_t \geq c \left[ 1 - O(\nabla) - O(\|t\|^{-(d-4)/2+\epsilon}) \right] \|t\|^{1-2\rho},$$ (3.8)
and thus prove Theorem 2.2 for the time-oriented models, assuming \( \tilde{\nu} \equiv \sup_x \nabla(x,0) \ll 1 \).

In the proof of (3.8), we will require \( p_c \leq 3/2 \), which is a consequence of \( \tilde{\nu} \ll 1 \) if \( d > 4 \) [18, 22, 24]. We will also assume existence of a constant \( \theta_1 > 1 \), which is independent of \( d \) and \( L \), such that \( \sum_{s \leq t/2} \tilde{\tau}_s \leq aC_1\|t\| \) (cf., (2.14)) and \( K \leq \theta_1\|t\|^p \leq aK \) for some \( K > 0 \), which may depend on \( d \) and \( L \). After the proof, we briefly discuss how to remove all these extra assumptions.

The survival probability \( \theta_t \) is the probability of the event that there is a path of occupied bonds from \((0,0)\) to \(\partial B_t\). This event can be decomposed into two disjoint events depending on whether or not \((0,0)\) is doubly connected to \(\partial B_t\), denoted by \((0,0) \to \partial B_t\), which means that there are at least two bond-disjoint occupied paths from \((0,0)\) to \(\partial B_t\). If \((0,0)\) is connected but not doubly connected to \(\partial B_t\), then there is an occupied pivotal bond \(b = (\tilde{b}, \bar{b})\) for \((0,0) \to \partial B_t\) such that \((0,0) \to \bar{b}, \bar{b} \to \partial B_t\) and \(C^b(0,0) \cap \partial B_t = \emptyset\), where \(C^b(0,0)\) is the set of sites in \(\mathbb{Z}^d \times \mathbb{Z}_+\), connected from \((0,0)\) without using \(b\). Restricting the location of \(\bar{b}\) in \(B_{t/2}\) gives

\[
\theta_t \geq \sum_{b,\tilde{b} \in B_{t/2}} \frac{1}{N} \mathbb{P}(\{(0,0) \to b, \tilde{b} \to \partial B_t, \ C^b(0,0) \cap \partial B_t = \emptyset\}), \tag{3.9}
\]

where we used \(p_c \geq 1\).

To investigate the right-hand side of the above inequality, we introduce the following two notions. For an event \(E\) and \(Z \subset \mathbb{Z}^d \times \mathbb{Z}_+\), let \(\{E \text{ on } Z\}\) be the set of bond configurations whose restriction on bonds \(b \) touching \(Z\) (i.e., \(b\) or \(\tilde{b}\) is in \(Z\)) are in \(E\). Similarly, we define the event \(\{E \text{ in } Z\}\) to be the set of bond configurations whose restriction on bonds \(b \) contained in \(Z\) (i.e., both \(b\) and \(\tilde{b}\) are in \(Z\)) are in \(E\). Then, we can rewrite the probability in the right-hand side of (3.9) as (see [13, Lemma 2.5])

\[
\mathbb{P}(\{(0,0) \to b, C^b(0,0) \cap \partial B_t = \emptyset\} \text{ on } C^b(0,0) \setminus \{b \to \partial B_t\} \text{ in } C^b(0,0)^c). \tag{3.10}
\]

By the “conditioning on cluster” technique [2, 12, 13], (3.10) equals

\[
\mathbb{E}\left(\mathbf{1}_{\{(0,0) \to b, C^b(0,0) \cap \partial B_t = \emptyset\}} \mathbb{P}(\tilde{b} \to \partial B_t \text{ in } C^b(0,0)^c)\right) \\
= \mathbb{P}((0,0) \to b, C^b(0,0) \cap \partial B_t = \emptyset) \mathbb{P}(\tilde{b} \to \partial B_t) \\
- \mathbb{E}\left(\mathbf{1}_{\{(0,0) \to b, C^b(0,0) \cap \partial B_t = \emptyset\}} \left[\mathbb{P}(\tilde{b} \to \partial B_t) - \mathbb{P}(\tilde{b} \to \partial B_t \text{ in } C^b(0,0)^c)\right]\right). \tag{3.11}
\]

First, we consider the first term in (3.11). By translation invariance and monotonicity, \(\mathbb{P}(\tilde{b} \to \partial B_t)\) is bounded from below by \(\mathbb{P}((0,0) \to \partial B_t)\). Since \(C^b(0,0) \subseteq C(0,0)\), the contribution to (3.9) is bounded from below by

\[
\mathbb{P}((0,0) \to \partial B_t) \sum_{b,\tilde{b} \in B_{t/2}} \frac{1}{N} \mathbb{P}((0,0) \to b, (0,0) \not\to \partial B_t) \geq C_1\|t\| \mathbb{P}((0,0) \to \partial B_t), \tag{3.12}
\]
where we used the definition of $D$ in (2.1) and Assumption 2.1. We now prove that the right-hand side of (3.12) is bounded from below by the same formula as in the right-hand side of (3.8). By restricting the number of occupied bonds growing out of $(o, 0)$ to two, $\mathbb{P}((o, 0) \Rightarrow \partial B_t)$ can be bounded from below by

$$
\left( \frac{p_c}{N} \right)^2 \left( 1 - \frac{p_c}{N} \right)^{N-2} \sum_{(x,y)} \mathbb{P}((x, 1) \to \partial B_t, (y, 1) \to \partial B_t, C(x, 1) \cap C(y, 1) = \varnothing \text{ in } B_t),
$$

(3.13)

where $\sum_{(x,y)}$ is the sum over all pairs of distinct sites in $\Omega$. We note that $p_c^2(1 - p_c/N)^{N-2}$ is always bounded from above by an $N$-independent constant, while it is bounded from below by $e^{-1}$ using $p_c \leq 3/2$. By conditioning on $C(x, 1)$, (3.13) equals

$$
\left( \frac{p_c}{N} \right)^2 \left( 1 - \frac{p_c}{N} \right)^{N-2} \sum_{(x,y)} \mathbb{E} \left( I_{\\{(x,1)\to\partial B_t\}} \mathbb{P}((y, 1) \to \partial B_t \text{ in } C(x, 1)^c) \right).
$$

(3.14)

If we ignore the condition “in $C(x, 1)^c$”, we obtain the main contribution $\frac{p_c^2}{N^2} \theta_t^2 \geq \frac{K^2}{\epsilon^2} \|t\|^{-2\rho}$.

The correction is

$$
\left( \frac{p_c}{N} \right)^2 \left( 1 - \frac{p_c}{N} \right)^{N-2} \sum_{(x,y)} \mathbb{E} \left( I_{\\{(x,1)\to\partial B_t\}} \mathbb{P}(\{(y, 1) \to \partial B_t \} \setminus \{(y, 1) \to \partial B_t \text{ in } C(x, 1)^c\}) \right).
$$

(3.15)

We need an upper bound on (3.15) to obtain a lower bound on the left-hand side of (3.12). Since the event inside $\mathbb{P}$ in (3.15) is the event that all occupied paths from $(y, 1)$ to $\partial B_t$ go through $C(x, 1)$, there must be a $(z, s) \in C(x, 1)$ such that $(y, 1) \to (z, s) \to \partial B_t$. By the Markov property, the expectation in (3.15) is bounded by

$$
\mathbb{E} \left( I_{\\{(x,1)\to\partial B_t\}} \sum_{(z,s) \in C(x,1)} \tau_{s-1}(z - y) \theta_{t-s} \right)
$$

$$
= \sum_{(z,s)} \mathbb{P}((x, 1) \to \partial B_t, (z, s) \in C(x, 1)) \tau_{s-1}(z - y) \theta_{t-s}.
$$

(3.16)

We consider $\sum_{s \leq t/2}$ and $\sum_{s > t/2}$ separately. For the former sum, we use the BK inequality to bound (3.16) by

$$
\sum_{s=2}^{t/2} \sum_{s'=1}^s \sum_{z,z' \in \mathbb{Z}^d} \tau_{s'-1}(z' - x) \tau_{s-s'}(z - z') \tau_{s-1}(z - y) \theta_{t-s} \theta_{t-s'}.
$$

(3.17)

Since $t - s' \geq t - s \geq t/2$ and $s \geq 2$ (because $x \neq y$), the contribution to (3.15) is bounded by $4^p(aK)^2 \overline{\nu} \|t\|^{-2\rho}$, where we used (2.5). On the other hand, we use (3.16) to bound the sum over $s > t/2$. If we ignore the condition $(x, 1) \to \partial B_t$, then (3.16) is bounded by

$$
\sum_{s=t/2}^t \hat{\tau}_{s-1} \hat{\tau}_{s-1} \theta_{t-s} \leq c \|t\|^{-d/2} \sum_{s=t/2}^t \|t - s\|^{-\rho}.
$$

(3.18)
Since $\rho \leq 1$, the right-hand side is further bounded by $c\|t\|^{-d/2+1-\rho+\epsilon} \leq c\|t\|^{-(d-4)/2+\epsilon}$. Therefore, (3.12) is bounded from below by

$$
\frac{C_1 K^2}{4e} (1 - 4^{\rho+1} e a^2 \nabla - c\|t\|^{-(d-4)/2+\epsilon})\|t\|^{1-2\rho}.
$$

(3.19)

Next, we investigate the second term in (3.11). Note that the event $\{b \nabla \partial B_t \setminus \{b \nabla \partial B_t \in C^b(0,0)^c\}$ implies existence of a $(z, s) \in C^b(0,0)$ such that $b \nabla \partial B_t$ and $b \nabla (z, s) \nabla \partial B_t$ occur disjointly. By the BK inequality and the definition (2.1), the contribution to (3.9) from the second term in (3.11) is bounded by

$$
\sum_{(z, s), (v, s') \setminus t} \mathbb{P}((o, 0) \nabla \partial B_t (z, s) \in C^b(0,0)) \tau_{z-s}(v) \theta_{t-s} \theta_{t-s'}
$$

(3.20)

where we used $s' \leq t/2$ to bound $\theta_{t-s'}$. We separate the sum over $s$ into $\sum s \leq 3t/4$ and $\sum s > 3t/4$. When $s \leq 3t/4$, we bound $\theta_{t-s}$ by $4^\rho aK\|t\|^{-\rho}$, and then bound the remaining term by $\sum_{r=0}^{t/2-1} \tau_r \sum_{r'=s+r}^{t} \sum_{x \in \mathbb{Z}^d} (\tau_{x-r} * D \tau_{x-s})(x) \tau_{s-r}(x) \theta_{t-s}$.

(3.21)

By summarizing the above estimates, (3.20) is bounded by

$$
(8^\rho a^3 C_1 K^2 \nabla + c\|t\|^{-(d-4)/2+\epsilon})\|t\|^{1-2\rho}.
$$

(3.22)

The proof of (3.8) is completed by (3.19) and (3.22).

We obtain (2.16) from (3.8) if $\tilde{\nabla} \ll 1$, $t \gg 1$ and $d > 4$. Together with $\rho \leq 1$ proved in Section 3.1, this completes the proof of $\rho = 1$.

Remark. In the above proof, we exploited the assumptions stated below (3.8). These assumptions can be removed via a delocalization argument [4] (or, it is also called ultraviolet regularization [2, 3, 12]). In fact, we can prove that there is a $c_t > 0$ such that

$$
t^{-\rho} \geq c_t [1 - O(\nabla t) - O(t^{-\rho})] t^{1-2\rho}, \quad \text{for } t \gg \ell.
$$

(3.23)
Recall that $(\alpha, \eta) = (2, 0)$ implies $\lim_{t \to \infty} \nabla_t = 0$, as explained below (2.11). Taking $\ell$ and $t$ in (3.23) sufficiently large, independently of $d$ and $L$, we obtain (2.16) for the time-oriented models. Therefore, we do not need the extra assumptions stated below (3.8).

We briefly explain the idea for the proof of (3.23). Recall (3.9), where $b$ is the last pivotal bond for $(o, 0) \to \partial B_t$. The space-time rectangle $\mathcal{R}_t(b)$ is defined as

$$\mathcal{R}_t(b) = \{ b + (re_b, s) \in \mathbb{Z}^d \times \mathbb{Z}_+ : r \in [-\ell, \ell], s \in [0, \ell] \},$$

where $e_b = (v - u)/(v - u)$ for $b = ((u, s), (v, s + 1))$. We may modify the occupation status of bonds contained in $\mathcal{R}_t(b)$, in order to thin the connection from $(o, 0)$ to $\partial B_t$. Let $E_{\mathcal{R}_t(b)}$ be such an event that $b$ is “minimally” connected, via $b$, to both $X_+ \equiv b + (\pm \ell e_b, \ell)$. Then, we obtain (cf., (3.9))

$$\theta_t \geq \sum_{b \in \mathcal{B}_{t/2}} \mathbb{P}(E_{\mathcal{R}_t(b)}) \mathbb{P}\left( (o, 0) \to b, C_{\mathcal{R}_t(b)} (o, 0) \cap \partial B_t = \emptyset, \{ X_+ \cap \partial B_t \} \cup \{ X_- \cap \partial B_t \} \right),$$

(3.25)

where $E_1 \circ E_2$ is the event that $E_1$ and $E_2$ occur disjointly, and $C_{\mathcal{R}_t(b)} (o, 0)$ is the set of sites connected from $(o, 0)$ without using any bonds contained in $\mathcal{R}_t(b)$. In (3.25), we used the fact that $E_{\mathcal{R}_t(b)}$ is independent of the other three events in $\mathbb{P}$. We choose $c_t = \inf \mathbb{P}(E_{\mathcal{R}_t(b)})$. For the remaining term, we follow the same strategy as in the proof for the case $\nabla \ll 1$, except that we do not need an argument around (3.13). This leads to (3.23).

It remains to determine $E_{\mathcal{R}_t(b)}$. This was well-explained in [4] for the time-discretized contact process. A variant of $E_{\mathcal{R}_t(b)}$ in [4] was chosen in such a way that $c_t$ is bounded away from zero uniformly in the discretized-time unit. It is not hard to adapt the idea of [4] to our settings, and we refrain from giving its details. See [4, Figure 1].

Proof for percolation. The strategy is the same as above. We prove below

$$\theta_t \geq c [1 - O(\nabla_0) - O(\|t\|^{-(d-5-\rho/2)} + \|t\|^{2-2\rho})],$$

for $t \geq 2L$ (so that $\partial B_{t/2} \subset B_t$), and hence Theorem 2.2 for percolation, assuming $\nabla_0 \ll 1$. Similarly to the proof for the time-oriented models, we will also assume that $p_c \leq 3/2$, which is indeed the case when $\nabla_0 \ll 1$ and $d > 6$ [11, 18], and that there is a $(d, L)$-independent constant $a > 1$ such that $\sum_{x \in B_{3t/2+L}} \tau(x) \leq a C_2 \|t\|^2$ (cf., (2.15)) and $K \leq \theta_t \|t\|^\rho \leq aK$ for some $K > 0$, which may depend on $d$ and $L$. These assumptions can be removed as discussed above and as in [2, 3, 12], and thus we omit its details for simplicity.

The percolation version of the joint inequality of (3.9)–(3.11) is

$$\theta_t \geq \sum_{b \in \mathcal{B}_{t/2}} \frac{1}{N} \mathbb{P}(o \leftrightarrow b^c, C^b (o) \cap \partial B_t = \emptyset) \mathbb{P}(b \leftrightarrow \partial B_t)$$

$$- \sum_{b \in \mathcal{B}_{t/2}} \frac{1}{N} \mathbb{E} \left[ \mathbb{1}_{\{o \leftrightarrow b^c, C^b (o) \cap \partial B_t = \emptyset\}} \left[ \mathbb{P}(b \leftrightarrow \partial B_t) - \mathbb{P}(b \leftrightarrow \partial B_t \text{ in } C^b (o)^c) \right] \right],$$

(3.27)
where “⇔” represents a double connection for percolation. Similarly to the argument around (3.12), by using \( \mathbb{P}(\tilde{\theta} \Leftrightarrow \partial B_1) \geq \mathbb{P}(\theta \Leftrightarrow \partial B_{3t/2}) \) and \( C^b(o) \subset C(o) \), together with the definition (2.1) and Assumption 2.1, the first sum in (3.27) is bounded from below by

\[
C_2 \| t \|^2 \mathbb{P}(o \Leftrightarrow \partial B_{3t/2}).
\]  

(3.28)

We first prove that (3.28) is bounded from below by the same formula as in the right-hand side of (3.26). There are minor changes to investigate \( \mathbb{P}(o \Leftrightarrow \partial B_{3t/2}) \), and now we discuss these modifications. Let \( \tilde{C}_{3t/2}(x) \subset B_{3t/2+L} \) be the set of sites to which there is an occupied path from \( x \) that includes at most one bond touching \( \partial B_{3t/2} \) and no bonds touching \( o \in \mathbb{Z}^d \). By restricting the number of occupied bonds touching \( o \in \mathbb{Z}^d \) to two, \( \mathbb{P}(o \Leftrightarrow \partial B_{3t/2}) \) is bounded from below by (cf., (3.13))

\[
\left( \frac{p_c}{N} \right)^2 \left( 1 - \frac{p_c}{N} \right)^{N-2} \sum_{(x,y)} \mathbb{P}(x \leftrightarrow \partial B_{3t/2} \in \{ o \}^c, \ y \leftrightarrow \partial B_{3t/2} \in \{ o \}^c, \ \tilde{C}_{3t/2}(x) \cap \tilde{C}_{3t/2}(y) = \emptyset).
\]

(3.29)

By conditioning on \( \tilde{C}_{3t/2}(x) \), the above expression equals

\[
\left( \frac{p_c}{N} \right)^2 \left( 1 - \frac{p_c}{N} \right)^{N-2} \sum_{(x,y)} \mathbb{E} \left[ \mathbb{1}_{\{ x \leftrightarrow \partial B_{3t/2} \in \{ o \}^c \}} \mathbb{P}(y \leftrightarrow \partial B_{3t/2} \in \{ o \}^c \cap \tilde{C}_{3t/2}(x)^c) \right]
\]

\[
= \left( \frac{p_c}{N} \right)^2 \left( 1 - \frac{p_c}{N} \right)^{N-2} \sum_{(x,y)} \left[ \mathbb{P}(x \leftrightarrow \partial B_{3t/2} \in \{ o \}^c) \mathbb{P}(y \leftrightarrow \partial B_{3t/2} \in \{ o \}^c) \right.
\]

\[
- \mathbb{E} \left( \mathbb{1}_{\{ x \leftrightarrow \partial B_{3t/2} \in \{ o \}^c \}} \mathbb{P}(\{ y \leftrightarrow \partial B_{3t/2} \in \{ o \}^c \} \setminus \{ y \leftrightarrow \partial B_{3t/2} \in \{ o \}^c \cap \tilde{C}_{3t/2}(x)^c \}) \right). \tag{3.30}
\]

Here, we have \( \mathbb{P}(x \leftrightarrow \partial B_{3t/2} \in \{ o \}^c) \), instead of \( \mathbb{P}(x \leftrightarrow \partial B_{3t/2}) \). The correction is the probability of the event that all occupied paths between \( x \) and \( \partial B_{3t/2} \) go through the origin, and thus is bounded by the probability of the event that \( x \leftarrow o \) and \( o \leftarrow \partial B_{3t/2} \) occur disjointly. By the BK inequality and monotonicity, we obtain

\[
\mathbb{P}(x \leftrightarrow \partial B_{3t/2} \in \{ o \}^c) \geq \mathbb{P}(x \leftrightarrow \partial B_{3t/2}) - \tau(x) \theta_{3t/2} \geq \theta_{3t/2+L} - \tau(x) \theta_{3t/2}. \tag{3.31}
\]

The contribution to (3.30) from \( \theta_{3t/2+L}^2 \) is bounded from below by \((4^{p+1}c)^{-1} R^2 \| t \|^{-2p} \), where we used \( p_c \leq 3/2 \) (cf., the argument below (3.13)) and \( t \geq 2L \) together with (2.5). Since \( N^{-2} = D(x) D(y) \) in (3.30), the contribution from the terms containing \( \tau(x) \theta_{3t/2} \) or \( \tau(y) \theta_{3t/2} \) is bounded by \( K^2 O(\mathbb{v}_0) \| t \|^{-2p} \).

To complete bounding (3.28), it suffices to prove that the expectation in (3.30) is bounded by

\[
(a^2 K^2 \mathbb{v}_0 + c \| t \|^{-(d-5-\rho/1)+\epsilon}) \| t \|^{-2p}. \tag{3.32}
\]
Since the event inside $\mathbb{P}$ is the event that all occupied paths from $y$ to $\partial B_{3t/2}$ in $\{o\}^c$ go through $\tilde{C}_{3t/2}(x) \subset B_{3t/2+L}$, there must be a $z \in \tilde{C}_{3t/2}(x)$ such that $y \leftrightarrow z$ and $z \leftrightarrow \partial B_{3t/2}$ occur disjointly. Therefore, the expectation in (3.30) is bounded, using the BK inequality, by
\[
\mathbb{E}\left(1_{x \leftrightarrow \partial B_{3t/2} \text{ in } \{o\}^c} \sum_{z \in \tilde{C}_{3t/2}(x)} \tau(z, y) \mathbb{P}(z \leftrightarrow \partial B_{3t/2})\right) \leq \sum_{z \in B_{3t/2+L}} \mathbb{P}(x \leftrightarrow \partial B_{3t/2}, z \in \tilde{C}_{3t/2}(x)) \tau(z, y) \mathbb{P}(z \leftrightarrow \partial B_{3t/2}). \tag{3.33}
\]
We separate the sum into $\sum_{z \in B_{3t/2+L} \setminus B_{t/2}}$ and $\sum_{z \in B_{t/2}}$. As in (3.18), by ignoring the condition $x \leftrightarrow \partial B_{3t/2}$ and using $\mathbb{P}(z \leftrightarrow \partial B_{3t/2}) \leq \theta_{(3t/2-|z|)\vee 0}$, the former sum is bounded by
\[
\sum_{z \in B_{3t/2+L} \setminus B_{t/2}} \tau(z-x) \tau(z-y) \theta_{(3t/2-|z|)\vee 0} \leq c\|t\|^{(d-1)+2(2-d)} \left(L + \sum_{s=0}^{t} \|s\|^{-\rho}\right) \leq c\|t\|^{-2\rho-(d-5-\rho\vee 1)+\epsilon}. \tag{3.34}
\]
This is further bounded by (3.32), because $\rho \leq 2$. For the sum $\sum_{z \in B_{t/2}}$, we first bound $\mathbb{P}(z \leftrightarrow \partial B_{3t/2})$ by $aK\|t\|^{-\rho}$. Then, note that the event inside the former $\mathbb{P}$ in (3.33) implies existence of $w \in B_{3t/2+L}$ such that $x \leftrightarrow w$, $w \leftrightarrow z$ and $w \leftrightarrow \partial B_{3t/2}$ occur disjointly. Again by the BK inequality, the contribution to (3.33) from $z \in B_{t/2}$ is bounded by
\[
aK\|t\|^{-\rho} \sum_{z \in B_{t/2}} \tau(z-x) \tau(z-y) \mathbb{P}(w \leftrightarrow \partial B_{3t/2}). \tag{3.35}
\]
We further separate the sum over $w$ into $\sum_{w \in B_{t/2}}$ and $\sum_{w \in B_{3t/2+L} \setminus B_{t/2}}$. For the former sum, we bound $\mathbb{P}(w \leftrightarrow \partial B_{3t/2})$ by $aK\|t\|^{-\rho}$, and then bound the remaining term by $\nabla_0$, using $x \neq y$. For the latter sum, we use $\mathbb{P}(w \leftrightarrow \partial B_{3t/2}) \leq \theta_{(3t/2-|w|)\vee 0}$ and perform the sum over $z$ using [10, Proposition 1.7(i)]. Since $x, y \in \Omega$, the expression (3.35) due to the sum over $w \in B_{3t/2+L} \setminus B_{t/2}$ is bounded by
\[
c\|t\|^{-\rho} \sum_{w \in B_{3t/2+L} \setminus B_{t/2}} \|w\|^{(2-d)+(4-d)} \left\|2t - |w|\right\|^{-\rho} \leq c\|t\|^{-\rho+6-2d+(d-1)} \left(L + \sum_{s=0}^{t} \|s\|^{-\rho}\right) \leq c\|t\|^{-2\rho-(d-5-\rho\vee 1)+\epsilon}. \tag{3.36}
\]

\[\text{Some readers might wonder whether the condition } x \leftrightarrow \partial B_{3t/2} \text{ could be used to have less power in (3.34). In fact, if we use the inequality}
\]
\[
\mathbb{P}(x \leftrightarrow \partial B_{3t/2}, z \in \tilde{C}_{3t/2}(x)) \leq \sum_{w \in B_{3t/2+L}} \tau(w-x) \tau(z-w) \theta_{(3t/2-|w|)\vee 0},
\]
\[\text{then the contribution due to } w \in B_{t/2} \text{ is bounded by (3.36), while the contribution from } w \in B_{3t/2+L} \setminus B_{t/2} \text{ has a worse bound } c\|t\|^{-2\rho+\mu}, \text{ where } \mu \text{ is negative only when } d > 9. \]
Summarizing the above estimates, we conclude that (3.28) is bounded from below by the same formula as in the right-hand side of (3.26), where a multiple constant corresponding to $c$ in (3.26) is $O(C_2 K^2)$. The second sum in (3.27) can be estimated similarly to (3.35), where $z$ in (3.35) corresponds to $\bar{b}$ in (3.27), and is bounded by a similar formula to (3.32), multiplied by $O(C_2 \|t\|^2)$. This completes the proof of (3.26).

We obtain (2.16) from (3.26) if $\nabla_0 \ll 1$, $t \gg 1$ and $d > 5 + \rho \vee 1$, and thus obtain $\rho = 2$ for $d > 7$. This completes the proof.

Remark. The value of $\rho$ for percolation is expected to be 2 as soon as $d > 6$. The main obstacle to going down from $d > 7$ is in (3.34) and (3.36), which correspond respectively to (3.18) and (3.21) for the time-oriented models. In (3.18) and (3.21), the sum over $s$ is fully controlled using $\theta_{t-s} \simeq \|t-s\|^{-\rho}$. On the other hand, the point-to-surface connectivity $\theta_{(3t/2-|v|)\cap B(0)}$, with $v = z$ in (3.34) and $v = w$ in (3.36), is insufficient to obtain the desired bound, when $v$ is close to the boundary $\partial B_{3t/2}$. This difficulty is considered to be caused by naively bounding the probability inside $\mathcal{E}$ in (3.30) as in (3.33). Since $\{y \leftrightarrow \partial B_{3t/2} \cap \mathcal{O} \cup \mathcal{C}_{3t/2}(x) \}$ is the event that all occupied paths from $y$ to $\partial B_{3t/2} \cap \mathcal{O} \cup \mathcal{C}_{3t/2}(x)$ have to go through $\mathcal{C}_{3t/2}(x)$ before reaching to the boundary, the approximation by the unrestricted two-point function $\tau(z-y)$ in (3.33) could be very crude when $z$ is close to $\partial B_{3t/2}$, due to the isotropic property for percolation. If we assume that there is a $\kappa \geq 1$ such that, for $|z| = \ell$,

$$
\mathbb{P}(o \leftrightarrow z, \ o \not\leftrightarrow B_{\xi}) \leq c \|\ell\|^{2-d-\kappa}(\|\ell\| \wedge \|t-\ell\|)^\kappa,
$$

(3.37)

then we will be able to obtain the desired inequality (2.16) down to $d > 6$. Note that (3.37) contains the factor $\|t-\ell\|$ that decreases as $z$ approaches the boundary $\partial B_{\xi}$, that the sum of the right-hand side over $z \in B_{\xi}$ is bounded by $c\|t\|^2$, and that the limit $t \to \infty$ of the right-hand side, while $\ell$ or $\ell/t$ is fixed, is $c\|\ell\|^{2-d}$. Therefore, (3.37) is a good candidate for the bound on the restricted two-point function, though we have not proved whether (3.37) really holds or does not. (For random walk, a similar inequality with $\ell = t$ and $\kappa = 1$ has been verified by our rough calculation.)

Acknowledgements

I am grateful to Federico Camia and Remco van der Hofstad for many valuable comments on the first draft of this paper. I would also like to thank Antal Járai and Frank den Hollander for stimulating discussions, and Takashi Hara for his unpublished manuscript. This work was supported by a Postdoctoral Fellowship of EURANDOM, the Netherlands.
