Document Version:
Publisher’s PDF, also known as Version of Record (includes final page, issue and volume numbers)

Please check the document version of this publication:

• A submitted manuscript is the version of the article upon submission and before peer-review. There can be important differences between the submitted version and the official published version of record. People interested in the research are advised to contact the author for the final version of the publication, or visit the DOI to the publisher’s website.
• The final author version and the galley proof are versions of the publication after peer review.
• The final published version features the final layout of the paper including the volume, issue and page numbers.

In a recent paper\textsuperscript{1} by Peeters \textit{et al.}, new experimental data on nucleation rates of water in helium in the temperature range of 200–235 K were presented. The original data are shown in Fig. 1. Nucleation rates have been reduced with classical nucleation theory predictions as described in the original paper.\textsuperscript{1} In this temperature range a drastic change in the nucleation process was observed at 207 K, which according to the author’s suggestion was due to a transition from vapor/liquid to vapor/solid nucleation. To investigate this phenomenon more carefully some additional experiments were made in the same temperature range and using the same experimental setup as well. The new measurements did not show any sign of such transition in the indicated temperature range. To explain the discrepancy, the raw data obtained by Peeters \textit{et al.} were closely investigated and an error was found in the calculation of the vapor fraction of water in the test gas mixture.

The test gas mixture originates from a combination of two different streams. One is a “wet” helium gas stream. This gas stream is saturated with water vapor by bubbling it through two containers, half-filled with water at a constant pressure and temperature. In that way, the wet gas stream has a constant vapor fraction. It can be diluted by the second gas stream, which consists of dry helium only. The gas streams are controlled by mass flow controllers (MFCs). Setting a different ratio of the flows through the MFCs alters the composition of the gas–vapor mixture.

The experimental setup allows measuring nucleation rates in a “window” between $10^{14}$ and $10^{17}$ m$^{-3}$ s$^{-1}$. For different temperature regions, different initial saturations have to be chosen. This is achieved by changing the degree of dilution of the wet gas stream. The error made by Peeters \textit{et al.} was that they used a wrong calibration curve for the MFC controlling the dry gas (helium) stream. As a result, the real vapor fraction in the test gas was lower than the calculated one. Peeters \textit{et al.} observed a sudden change in nucleation rates (Fig. 1) at 207 K. It has become clear now that the nucleation rate jump was caused by a discontinuous change in the dilution procedure at 207 K. The raw data of Peeters \textit{et al.} have been reinterpreted using the correct calibration data and they are shown in Fig. 1. The recalculated data in tabulated form can be obtained directly from the authors by e-mail or from EPAPS.\textsuperscript{2} The corrected data agree quite well with the data by Wölk and Strey\textsuperscript{3} (see Fig. 1). Wölk and Strey obtained their data using a completely different type of experimental setup.
