In 2004, it was discovered that a free-standing single atomic layer can be isolated from its environment by means of micromechanical cleavage. Of the different reported two-dimensional crystals, the single atomic layer of graphite, graphene, has gained most interesting due to its remarkable electronic properties. The vast majority of the studies focuses therefore on its electronic properties. Its optical properties, however, were less explored.

Gray et al. studied the optical properties of graphene by near-normal incidence reflectance measurements in the range 190–1000 nm. They acquired reflectance data of graphite flakes of different thicknesses, down to graphene, deposited on a silicon wafer with 300 nm silicon dioxide (SiO₂) on top. They assumed the optical constants to be independent of thickness and that they could be parameterized with five Forouhi–Bloomer oscillators. The parameters of these oscillators and each thickness were fitted simultaneously to all the reflectance data. The thickness was fitted as 3.8 Å. This work was extended by adding spectroscopic ellipsometry and reflectance data. The thickness was fitted as 3.8 Å. This work

was extended by adding spectroscopic ellipsometry and reflectance data. The thickness was fitted as 3.8 Å. This work

lateraters and each thickness were fitted simultaneously to all the

dispersion parameters of graphene as found from spectro-

sometric data by numerical inversion in the dispersion parameters, an optical model is required that

describes the sample’s optical response. It consists of the thickness and (parameterizations for) the optical constants of every layer in the sample. The “goodness-of-fit” of the model to the experimental data is determined by the reduced chi-

squared unbiased estimator, \( \chi^2 \), for the three Stokes parameters \( S_1 \) to \( S_3 \)

squerred unbiased estimator, \( \chi^2 \), for the three Stokes parameters \( S_1 \) to \( S_3 \)

thickness of graphene. The thickness is in perfect agreement with the thickness as expected from the interlayer spacing in graphite: 3.4 Å. Based on the found optical constants we have simulated transmittance for graphene. We show that this simulation is in better agreement with measured transmittance than the transmittance that we simulated based on optical constants from other work.

Ellipsometry can measure the change in polarization of light after reflection from a sample. This change is measured as the ratio of the Fresnel reflection coefficients for the \( p \) and \( s \) component of the reflected light, denoted as \( r_p \) and \( r_s \), respectively. This ratio, \( \rho \), is in general a complex number and commonly expressed as \( \rho = r_p / r_s = \tan \Psi \exp i \Delta \), where \( \Psi \) and \( \Delta \) are the ellipsometric angles.

We used an automated angle M-2000F rotating compensator ellipsometer with a 300 mm X-Y mapping stage and focusing probes, and the accompanying software Complete-EASE 4.27 from J.A. Woollam Co., Inc. A rotating compensator ellipsometer can measure all of the four Stokes parameters, \( S_0 \) to \( S_3 \), in a single measurement. The degree of depolarization, defined as \( p = (S_1^2 + S_2^2 + S_3^2)^{1/2} / S_0 \), for the measurements on graphene is on average 1.3%. The ellipsometric data were acquired in the wavelength range \( \lambda = 210–1000 \) nm with a resolution of \( \Delta \lambda \approx 1.6 \) nm at an angle of incidence \( \theta = 55° \). At this angle the spot size is small enough to acquire several scans from the graphene flake. The acquisition time per measurement is 1 min, resulting in a very high signal to noise ratio. Our single layer graphene was prepared by mechanical cleavage of natural graphite (NGS Naturgraphit GmbH). Raman measurements at 514 nm, confirmed that it is a monolayer: the intense 2D-peak at \( 2690 \) cm\(^{-1}\) and the intense G-peak at \( 1580 \) cm\(^{-1}\) correspond to the peaks for graphene.

To extract optical constants and thickness of a sample from ellipsometric data, an optical model is required that describes the sample’s optical response. It consists of the thickness and (parameterizations for) the optical constants of every layer in the sample. The “goodness-of-fit” of the model to the experimental data is determined by the reduced chi-

squared unbiased estimator, \( \chi^2 \), for the three Stokes parameters \( S_1 \) to \( S_3 \)
Once the optical response of the underlying layers is characterized very accurately, the third layer for graphene is added for the analysis of the measurements on graphene. Since we want to determine the optical constants and thickness of graphene independently, we do not use numerical inversion, assuming a thickness. Instead, we use a parameterization for the optical constants. Since we do not want to assume any physical oscillator parameterization beforehand, we use a B-spline function, which is defined as a linear sum of B-splines

\[ S(x) = \sum_{i=1}^{n} c_i B_i^1(x), \]

in which \( c_i \) are the B-spline coefficients. B-splines are a special set of piecewise defined polynomials and can be given by the following recursive formula:

\[ B_i^1(x) = \begin{cases} 1 & t_i \leq x \leq t_{i+1} \\ 0 & \text{otherwise} \end{cases}, \]

\[ B_i^1(x) = \frac{x-t_i}{t_{i+k}-t_i} B_{i+k}^1(x) + \frac{t_{i+k+1}-x}{t_{i+k+1}-t_{i+1}} B_{i+1}^1(x), \]

in which \( t \) are the abscissa of the knots, which are the points where the polynomials connect, and \( k \) is the B-spline degree. For \( n \) knots there are \( n-k+1 \) coefficients; no coefficients exist for \( t_1, \ldots, t_{k-1} \) and \( t_{n-k+2}, \ldots, t_n \). The B-spline coefficients are the fit parameters whereas the knots are chosen. Since a Kramers–Kronig (KK) transformation exists for a B-spline function, we can enforce KK consistency on our optical constants during fitting. This not only ensures a physical solution but also reduces the number of fitting parameters by two, since now only \( n \) needs to be found and \( k \) can be found from the KK transformation (or vice versa). Our analysis software can only report coefficients for the imaginary part of the dielectric function, \( \varepsilon_2 \), as a function of energy: \( \varepsilon_2(E) = \sum_{i=1}^{n} c_i B_i^1(E) \) (the real part of the dielectric function, \( \varepsilon_1 \), is found from the KK transformation). We therefore report \( t_1 \) in electronvolt and \( c_i \) for \( \varepsilon_2 \). Since a B-spline function has ultimate shape control it can follow all the features in the optical function, depending on the amount of knots, while still being KK consistent.

To determine the thickness and optical constants of graphene, only these data should be analyzed that are acquired from the graphene flake and not also partially from the SiO\(_2\). The graphene flake is \( \sim 150 \times 380 \ \mu m^2 \), and we measured the full width at half maximum spot size as \( \sim 100 \times 55 \ \mu m^2 \) with a knife-edge type of technique. Since the scan step size is 50 \( \mu m \), there should be several measurements only on the graphene flake, showing the same spectra. We identified eight spots of which the spectra overlapped. These eight spots are shown as the white dots in Fig. 1(b). The shape that encloses the white spots is similar to that of the picture of Fig. 1(a).

The optical model is fitted to these eight spectra simultaneously. The B-spline parameterization has a degree \( k=3 \). We chose ten knots, with a spacing of 0.5 eV in the measured range, and three knots outside the measured range. One of these three knots is necessary for absorption in the infrared and the other two for absorption in the ultraviolet range. The outer four knots ensure that \( \varepsilon_2 \) goes smoothly to zero. A total of thirteen coefficients is fitted. This number of coefficients

\[ \Delta \text{ at } \lambda = 590 \text{ nm} \]

\[ \Delta \text{ at } \lambda = 590 \text{ nm} \]

FIG. 1. (Color online) (a) An optical microscope image of graphene exposed to visible light. The darker part is multilayer graphene. (b) A spectroscopic ellipsometric scan of the flake showing a map of \( \Delta \) at 590 nm. The white dots indicate the positions from which the spectra can be attributed to originate from the graphene only. The shape that encloses the white spots is similar to that of the flake.

\[ \chi^2_{\text{red}} = \frac{1}{3n-m} \sum_{i=1}^{n} \sum_{j=1}^{3} \left( \frac{S_{ij}^{\text{exp}} - S_{ij}^{\text{mod}}}{\sigma_{ij}^{\text{exp}}} \right)^2, \]

where \( n \) is the number of wavelengths, \( m \) is the number of fit parameters and \( \sigma_{ij}^{\text{exp}} \) is the error in the determined Stokes parameter. This error is assumed to be equal for all three parameters and for all wavelengths: \( \sigma_{ij} = 0.001 \). While fitting, \( \chi^2_{\text{red}} \) is minimized by the Levenberg–Marquardt nonlinear regression algorithm.

We study a three layer structure consisting of a single side polished crystalline silicon (c-Si) substrate, a SiO\(_2\) layer, and graphene. To determine the optical constants and thickness of graphene as accurately as possible, it is crucial that the optical response of the underlying layers is well known. We therefore acquire data of four spots next to the graphene flake. Since the optical constants of c-Si are well known from literature\(^{12} \) and the substrate can be considered to have a semi-infinite thickness, it is only necessary to find the SiO\(_2\) thickness and optical constants, which we first parameterize with a Sellmeier dispersion relation.\(^{11} \) For the four measurements simultaneously, the three Sellmeier parameters and for all wavelengths: \( \alpha_S = 0.001. \) While fitting, \( \chi^2_{\text{red}} \) is minimized by the Levenberg–Marquardt nonlinear regression algorithm.

Our analysis software can only report coefficients for the imaginary part of the dielectric function, \( \varepsilon_2 \), as a function of energy: \( \varepsilon_2(E) = \sum_{i=1}^{n} c_i B_i^1(E) \) (the real part of the dielectric function, \( \varepsilon_1 \), is found from the KK transformation). We therefore report \( t_1 \) in electronvolt and \( c_i \) for \( \varepsilon_2 \). Since a B-spline function has ultimate shape control it can follow all the features in the optical function, depending on the amount of knots, while still being KK consistent.

To determine the thickness and optical constants of graphene, only these data should be analyzed that are acquired from the graphene flake and not also partially from the SiO\(_2\). proved to be sufficient to achieve both a very good fit and still be small enough to avoid correlation between all the fit parameters. Together with fitting the thickness a $\chi_{\text{red}}=2.454$ is obtained, which means a very good fit considering that eight spectra are fitted simultaneously.

The thickness was fitted as $3.4 \pm 0.04 \text{ Å}$. To test its uniqueness, the thickness is changed over a range of values. At each value, the thickness fit parameter is fixed while all other fit parameters are varied to find the lowest $\chi_{\text{red}}$. The uniqueness of the fitted thickness is shown in the inset of Fig. 2: a minimum for $\chi_{\text{red}}$ is at $3.4 \text{ Å}$. In Table I the B-spline knots and coefficients are shown. In Fig. 2 the optical constants, $n$ and $k$, of graphene are shown as functions of wavelength. An intense peak in $k$ is observed at 270 nm (4.6 eV). This peak can be attributed to the effect of strong resonant excitons.\textsuperscript{17} Compared to Kravets et al.\textsuperscript{5} the optical constants in Fig. 2 are smooth and KK consistent and the peak at 270 nm is even more intense.

Based on these optical constants we simulated the transmittance for freestanding graphene and compared it to the transmittance as measured by Nair et al.\textsuperscript{6} and as modeled from the optical constants found by Gray et al.\textsuperscript{3} and Bruna and Borini.\textsuperscript{7} The latter used the measured transmittance by Nair et al.\textsuperscript{6} and modeled the optical constants of graphene in the visible wavelength range by a constant refractive index and a linear dispersion for the extinction coefficient: $n=3$ and $k=(C_1/n)\lambda$, with $C_1=5,446 \text{ µm}^{-1}$. The comparison in Fig. 3 shows that the transmittance as modeled from the optical constants in this work agrees better with the measured transmittance than the transmittance as modeled from the optical constants by Gray et al.\textsuperscript{3}. It also agrees better than the modeled transmittance of Bruna and Borini,\textsuperscript{7} especially towards higher energies where there is the onset of the absorption peak at 4.6 eV.

In summary, spectroscopic ellipsometry in combination with a B-spline parameterization, allowed an accurate determination of the thickness of graphene and its KK consistent optical constants for the range 210–1000 nm. The thickness was fitted as $3.4 \text{ Å}$, which is in perfect agreement with the interlayer spacing in graphite. Based on the optical constants we simulated transmittance for freestanding graphene in the visible range and found good agreement with measured transmittance.
