Plasma-assisted atomic layer deposition (ALD) was used to deposit SiO$_2$ films in the temperature range of $T_{\text{dep}} = 50$–400°C on Si(100). H$_2$Si[N(C$_2$H$_5$)$_2$]$_2$ and an O$_2$, plasma were used as Si precursor and oxidant, respectively. The ALD growth process and material properties were characterized in detail. Ultrashort precursor doses (50 ms) were found to be sufficient to reach self-limiting ALD growth with a growth-per-cycle of $\sim 1.2$ Å ($T_{\text{dep}} = \sim 200°C$) leading to SiO$_2$ films with O/Si ratio of $\sim 2.1$. Moreover, the plasma ALD process led to a high conformity (95–100%) for trenches with aspect ratios of $\sim 30$. In addition, the electronic (interface) properties of ultrathin ALD SiO$_2$ films and ALD SiO$_2$/Al$_2$O$_3$ stacks were studied by capacitance-voltage and photoconductance decay measurements. The interface quality associated with SiO$_2$ was improved significantly by using an ultrathin ALD Al$_2$O$_3$ capping layer and annealing. The interface defect densities decreased from $\sim 1 \times 10^{12}$ eV$^{-1}$ cm$^{-2}$ (at mid gap) for single layer SiO$_2$ to $< 10^{11}$ eV$^{-1}$ cm$^{-2}$ for the stacks. Correspondingly, ultralow surface recombination velocities $< 3$ cm/s were obtained for n-type Si. The density and polarity of the fixed charges associated with the stacks were found to be critically dependent on the SiO$_2$ thickness (1–30 nm).

The key importance of thermally grown silicon dioxide (SiO$_2$) for applications in silicon-based microelectronics needs no introduction.$^{1,2}$ Also in silicon photovoltaics, SiO$_2$ is a very important material. The low interface defect densities associated with the Si/SiO$_2$ interface reduce surface recombination significantly and have enabled high solar cell efficiencies.$^{3-6}$ Temperatures $> 800°C$ are typically required to form SiO$_2$ by thermal oxidation of Si. Alternative methods for the synthesis of SiO$_2$ have been developed to avoid such high temperatures and long processing times. They may also enable single side deposition and a high level of control of the material properties and film thickness. These alternative methods include (wet) chemical oxidation, (plasma-enhanced) chemical vapor deposition, sputtering and electron beam evaporation.

Atomic layer deposition (ALD) is an alternative CVD-like method that recently gained considerable attention. In ALD, the substrate is sequentially exposed to two precursors (e.g., a Si-precursor and an oxidant) which each react with the surface until saturation. ALD allows for precise thickness control, optimal large-area uniformity, and the conformal coating of demanding substrate topologies.$^{7-9}$ Therefore, the advantages of ALD may expand the range of applications for SiO$_2$. ALD SiO$_2$ films may find application as protective or insulator coating, or can be used in nanolaminate structures with tailored electronic properties.$^{10,11}$ The films can also be used in spacer defined double patterning processes for example for dynamic random access memory (DRAM) technology.$^{12}$ In addition, the ALD SiO$_2$ process may be useful for engineering the interface between Si and high-k materials.$^{13}$ In Si photovoltaics, SiO$_2$ can be used in double-layer surface passivation schemes, for example comprising Al$_2$O$_3$ or a-SiN$_x$:H capping layers, with tailored interface properties.$^{14-18}$

In the first reports, ALD SiO$_2$ was synthesized employing SiCl$_4$ and H$_2$O which required relatively high substrate temperatures (>300°C) and long precursor exposures.$^{17,18}$ In recent years, various alternative Si precursors have been tested in combination with O$_2$ or H$_2$O as the oxidants. These processes include the use of pyridine (C$_5$H$_5$N) and Al as catalysts on the surface.17 $^{17,11,19}$ The approach employing Al was referred to as rapid ALD as it resulted in deposition rates above the “theoretical” maximum of one monolayer per ALD cycle. In addition, more recently a thermal ALD process for low-temperature SiO$_2$ was reported which was free of catalysts or corrosive by-products.$^{20}$ In this respect, the use of precursors with amino ligands has also shown promising results, in particular when combined with H$_2$O, O$_2$, or O$_3$ plasma as the oxidant.$^{21-24}$ Very recently, also SiH$_4$ has been used as Si precursor during plasma-assisted ALD with CO$_2$ plasma as oxidant.$^{25}$ SiO$_2$ films grown with ALD have been reported to exhibit low carbon content, and a high electrical breakdown field.$^{10,22}$ Nevertheless, to improve properties such as the chemical etch rate or the interface defect density, annealing at a temperature of 1000°C was shown to be beneficial.$^{20}$ Here, we report on a plasma-assisted ALD process for synthesis of SiO$_2$ at low substrate temperatures of 50–400°C. The ALD process employed H$_2$Si[N(C$_2$H$_5$)$_2$]$_2$ as the Si precursor (Figure 1). The plasma-assisted ALD process was characterized in detail and the results are compared to the well-understood thermal ALD process of Al$_2$O$_3$ using Al(CH$_3$)$_3$. We show that the ALD SiO$_2$ process was compatible with short cycle times and led to an excellent conformity even on structures with an aspect ratio of $\sim 30$. The electronic properties of the Si(100)/SiO$_2$ interface were investigated using photocapacitance decay and capacitance-voltage measurements. We demonstrate that interface defect densities $< 10^{11}$ eV$^{-1}$ cm$^{-2}$ (at mid gap) can be reached when using ultrathin Al$_2$O$_3$ capping layers and annealing at moderate temperatures ($\sim 400°C$).

The paper is organized as follows. After the experimental details, the characterization of the ALD SiO$_2$ process will be presented. In addition, the material properties and the influence of the substrate temperature will be addressed and data with respect to the conformality will be presented. Subsequently, a brief discussion on the surface chemistry is included on the basis of in situ measurements. The final sections discuss the surface passivation properties and the electronic (interface) properties of the SiO$_2$ films and SiO$_2$/Al$_2$O$_3$ stacks.

### Experimental

The SiO$_2$ films were deposited in the Oxford Instruments OpAL reactor. This is an open-load system, suited for both plasma and thermal ALD and operating at typical pressures of 150 mTorr. A remote O$_2$ plasma was used during the oxidation step in the ALD cycle. H$_2$Si[N(C$_2$H$_5$)$_2$]$_2$ (SAM.24, Air Liquide) was used as the Si precursor (Fig. 1). This is a liquid (melting point $< -10°C$) which each react with the surface until saturation. ALD process employed H$_2$Si[N(C$_2$H$_5$)$_2$]$_2$ as the Si precursor and oxidant.21 $^{17,11,19}$ The approach employing Al was referred to as rapid ALD as it resulted in deposition rates above the “theoretical” maximum of one monolayer per ALD cycle. In addition, more recently a thermal ALD process for low-temperature SiO$_2$ was reported which was free of catalysts or corrosive by-products.20
as no evidence was found for reactions between the Si precursor and O₂ under the experimental conditions used. The substrate temperature during deposition, T_

Figure 1. Vapor pressure of the H₂Si[N(C₂H₅)₂]₂ (SAM.24) precursor used for ALD of SiO₂ as a function of the temperature. The vapor pressure is compared to the one of Al(CH₃)₃ (TMA). This precursor is commonly used for ALD of Al₂O₃. The precursors are schematically represented in the figure.

Figure 2. SiO₂ film thickness as a function of the number of ALD cycles. (a) Substrate temperatures of 50°C, 200°C and 250°C. The film thickness was measured by in situ spectroscopic ellipsometry (SE). (b) SiO₂ film thickness extracted from the transmission electron microscopy (TEM) image of Fig. 3, compared with values determined by in situ SE on the same sample. The substrate temperature T_

Figure 3. High-resolution cross-sectional TEM image of a stack with alternating layers of ALD Al₂O₃ and ALD SiO₂ deposited using 10–40 cycles each. The substrate temperature was 200°C. The extracted layer thicknesses are shown in Fig. 2b.

ALD Process and Material Characterization

The ALD process was monitored by in situ spectroscopic ellipsometry (SE) by taking data points after a certain number of cycles. The SiO₂ film thickness is plotted as a function of the number of ALD cycles in Fig. 2a for substrate temperatures of 50°C, 200°C and 250°C. For the latter two temperatures, the SiO₂ thickness increased linearly with the number of cycles. A slight non-linearity was observed for T_

Figure 4 shows the effect of the duration of the successive steps in the ALD recipe, i.e., the precursor dosing, precursor purge step, plasma exposure, and plasma exposure purge step. In the corresponding experiments one process parameter in the ALD recipe was varied whereas the duration of the other steps was taken sufficiently long to
guarantee saturated ALD conditions for the non-varied process parameters. The substrate temperature was set to 250 °C. The growth process of SiO2 is compared to plasma-assisted ALD of Al2O3 at 250 °C (Figures 4e–4h). From the figure it is evident that ultrashort precursor dosing times (~50 ms) were already sufficient to reach self-limiting growth with a GPC of ~1.1 Å. These short dosing times were only slightly higher compared to those used for the Al(CH3)3 precursor for ALD of Al2O3. The fact that short dosing times are sufficient is in agreement with the expectations based on the relatively high vapor pressure of the SAM.24 precursor. Many processes for other oxides using different precursors require much longer dosing times. For instance, ALD of TiO2 and Ta2O5 require dosing times >1 s using alkylamide precursors in a similar remote plasma and thermal ALD reactor. The duration of the purge step after precursor dosing was required to be >2 s. For shorter purge times, residual precursor remaining in the reactor volume can react in the plasma, causing parasitic (PE) CVD-like growth and a higher GPC value. Regarding the O2 plasma step, a plasma exposure time > 1 s was found to be sufficient to reach a saturated GPC, indicating the rapid removal of the precursor ligands. For very short plasma exposure times, a drop in the refractive index below ~1.46 was observed. This decrease can be attributed to the incorporation of impurities in the SiO2 film that originate from the Si precursor. The plasma exposure time required for ALD SiO2 is slightly shorter than for plasma ALD of Al2O3 which requires plasma times of ~2 s to reach saturated growth. However, with in situ spectroscopic ellipsometry only the center of the Si wafer is probed and to ensure saturation over the full wafer surface, a plasma exposure time of 4 s was employed in all subsequent experiments. Interestingly, the purge after the plasma step had a significant impact on the GPC. This is in contrast to the ALD process for Al2O3, where the purge step after O2 plasma exposure was found to have little influence on the GPC and could be reduced well below 0.5 s. We attribute the higher GPC for shorter purges (< 2 s) to reactions between residual H2O2 formed during the plasma process, with the Si precursor injected in the subsequent step. Although it is known that the H2Si[N(C2H5)2]2 precursor reacts with H2O, it is relevant to mention here that we were unable to develop a thermal ALD process for SiO2 using SAM.24 as precursor and H2O as the oxidant. No film growth was observed. Instead, even with the shortest possible H2O doses applied, powder formation occurred in the reactor as was noticeable by the naked eye.

The thickness uniformity of the SiO2 films deposited by plasma-assisted ALD at 250 °C was evaluated by mapping the thickness by spectroscopic ellipsometry. A precursor dose time of 50 ms was used, while all other steps in the ALD cycle (Fig. 4) were set to 3 s. For a 8 inch (~200 mm) wafer the nonuniformity, defined by the difference between the maximum and minimum thicknesses divided by twice the average thickness of all data points measured,26 was < 3.5%. The thickness nonuniformity achieved on 4 inch (100 mm) wafers was ~1%.

Material properties and role of substrate temperature.— Figure 5 shows the effect of the substrate temperature between 50 and 400 °C on the growth rate and refractive index of SiO2. The length of the purge steps in the lower temperature regime was extended (up to 10 s
at 50 °C, as it is more difficult to remove H₂O at lower temperatures which could impact the saturation behavior of the process. The GPC was observed to decrease with increasing deposition temperature from ∼1.7 Å/cycle at 50 °C to 0.8 Å/cycle at 400 °C. The refractive index was fairly constant with a value of n = 1.46 ± 0.02 (photon energy of 2 eV) between 100 and 300 °C. Below 100 °C and above 300 °C the refractive index was somewhat lower. It can therefore not be excluded that some non-ideal ALD behavior takes place at the lowest and highest temperatures investigated. At the low substrate temperature of 50 °C, additional CVD reactions may contribute to the higher GPC and lower n. This might also explain the slightly non-linear trend between the film thickness and number of cycles observed at this deposition temperature as shown in Figure 2. Despite the long purging times (10 s) after the plasma step, the accumulation of some residual H₂O in the reactor, with which the precursor can react, may play a role in these observations. For temperatures reaching 400 °C, thermal stability issues of the precursor and its ligands can start to play a role.

Table I shows RBS and ERD data obtained for substrate temperatures of 100, 200 and 300 °C. The table shows that the number of Si atoms deposited per cycle decreases with increasing substrate temperature. This clearly demonstrates that the decrease of the GPC with increasing substrate temperature can be attributed to reduced precursor adsorption per cycle at higher temperatures. Similar results were obtained for Al₂O₃ synthesized by plasma-assisted ALD, 27, 31 which could be attributed almost fully to the decrease in the number of Al atoms deposited per cycle for increasing substrate temperatures. For Al₂O₃, the decrease in GPC with increasing temperature is mainly due to a loss of –OH surface groups due to thermally activated dehydroxylation reactions. 8, 33, 34 The similarity between both ALD processes indicates that the OH surface coverage is also a key parameter controlling the growth rate of ALD SiO₂ as will be discussed in more detail later.

The fact that good SiO₂ material properties were obtained between 100 and 300 °C can be concluded from Table I. The Si and O content correspond with an O/Si ratio of 2.1 ± 0.1 and the hydrogen content of the films is 7 – 10 at% depending on the substrate temperature. The carbon and nitrogen content of the films was below the detection limit of the RBS measurements of ∼5 at%. Apart from the hydrogen content, the material properties were found to be virtually independent of the substrate temperature in the range of 100–300 °C. This also holds for the mass density which was found to be 2.0 ± 0.1 g/cm³.

Fourier transform infrared absorption spectroscopy was used to compare the ALD SiO₂ films with thermally-grown SiO₂. Figure 6 shows the FTIR spectra. The data reveal a shift of the Si-O-Si stretching and Si-O-Si rocking modes toward lower wavenumbers of 2.2 g/cm³. The FTIR data also confirm the presence of hydrogen in the ALD SiO₂ films by the observation of S-O-H bending (∼920 cm⁻¹) and Si-O-H stretching (2500-3600 cm⁻¹) signatures in the spectrum.

Surface Morphology.— The surface morphology of the SiO₂ films was studied by AFM in semi-contact mode. A root-mean-square surface roughness of 1.9 and 1.6 Å was obtained for films deposited at 100 °C (film thickness 51 nm) and 200 °C (48 nm), respectively. The fact that these values were not higher than those obtained for uncoated polished Si wafers demonstrates that the SiO₂ films were deposited with negligible roughening on the Si(100) substrate. The latter can also be appreciated from the interface morphology as visualized in the TEM image of a SiO₂/Al₂O₃ stack displayed in Fig. 7. Perfectly smooth Si/SiO₂ and SiO₂/Al₂O₃ interfaces can be observed. From the AFM data, it also follows that the aforementioned small (PE)CVD growth component at low substrate temperatures is not pronounced yet at 100 °C as this would likely have resulted in enhanced surface roughness.

Conformality.— The conformality of the ALD process was examined on a structure with high-aspect ratio trenches using high-resolution SEM. The various trenches exhibited aspect ratios (AR, i.e., depth of trench divided by average width) between ∼10 and ∼30 and were fabricated by deep reactive ion etching (DRIE). The trenches exhibited a thermal SiO₂ layer of ∼100 nm on the surfaces. To obtain sufficient optical contrast between the layers, an Al₂O₃ film was deposited prior to ALD SiO₂ deposition. The length of the various steps in the ALD SiO₂ recipe was increased slightly compared to the requirements for ALD growth on a planar surface (see Fig. 4). The recipe included a dose time of 90 ms, a purge time of 5s, a plasma time of 4.5s and a subsequent purge time of 6s. Figure 8 shows the SEM image of a trench with an aspect ratio of AR = ∼30. The SiO₂ film was deposited using 830 cycles. The film thickness at the surface was determined with SEM to be 100 ± 5 nm, which was in good agreement with the 102 ± 1 nm obtained by spectroscopic ellipsometry for a planar reference sample. At the bottom of the trench a thickness of 95 ± 5 nm was extracted from the SEM graph. This demonstrates a very high conformality (95–100%) for the plasma-assisted ALD process. These results are important as there is only a limited amount of literature available on the conformality of plasma-assisted ALD processes (see Ref. 35 and references therein). For example, good results have previously been reported for AR up to ∼15. 36

![Figure 6. FTIR spectra of ALD SiO₂ prepared at 200 °C (48 nm film thickness) and thermal SiO₂ grown by wet oxidation at ∼900 °C (295 nm film thickness). The most prominent absorption peaks have been assigned (see Ref. 37 and references therein). The absorbance is normalized by the film thickness. A Si wafer without SiO₂ served as a reference to obtain the absorption spectra.](http://www.ecsdl.org/terms_use.jsp)
Surface Chemistry

From the data presented and on the basis of literature reports, some aspects of the surface chemistry during ALD SiO₂ can be briefly addressed. As mentioned previously, from the decrease of the GPC for increasing substrate temperatures (Fig. 5b), we can conclude that the ALD process is governed by surface chemical reactions involving –OH groups. Note here that the presence of residual –OH groups was demonstrated by the FTIR spectrum showing a clear signature of SiO-H bonds in the films (Fig. 6). During the precursor step, it is therefore most likely that the –N(C₂H₅)₂ ligands of the precursor react with the surface –OH groups producing volatile HN(C₂H₅)₂. A reaction involving the breaking of the Si-H bond in the precursor is very unlikely. We propose therefore similar surface chemical reactions during the first ALD half cycle as reported by Burton et al. for the SiH(N(CH₃)₂)₃ precursor which is comparable to the present precursor:

\[
\text{Si}-\text{OH}^+ + \text{H}_2\text{Si}[\text{N(C₂H₅)₂}]_2 \rightarrow \text{SiO}^- + \text{SiH}^- + [\text{N(C₂H₅)₂}]_2 + x \text{HN(C₂H₅)₂},
\]

where surface species are indicated by \(^\ddagger\). In this precursor adsorption reaction, only one \((x = 1)\) or both \((x = 2)\) of the –N(C₂H₅)₂ ligands may react. In the second half cycle, the surface reactions will be dominated by O radical species delivered by the plasma. From similar cases studied previously (e.g., Al₂O₃ from Al(CH₃)₃ and O₂ plasma and Ta₂O₅ from Ta[N(CH₃)₂]₃ and O₂ plasma) it can be hypothesized that combustion-like reactions dominate:

\[
\text{SiH}_2\text{N(C₂H₅)₂} + \text{O} \rightarrow \text{Si}-\text{OH}^+ + \text{H}_2\text{O} + \text{CO}_2 + \text{other (N-containing) species}
\]

In the latter expression the species are not balanced as it is unclear what reaction products are actually created. In the second half cycle also N-containing species need to be produced for the case that not all precursor molecules react with the –OH covered surface through the release of both –N(C₂H₅)₂ ligands, i.e. when \(x \neq 2\) for all precursor molecules adsorbing.

Evidence for the fact that \(x \neq 2\) for all precursor molecules was obtained from quadrupole mass spectrometry (QMS) measurements. Figure 8 shows time-dependent mass spectrometry data for a number of selected mass-over-charge \(m/z\) ratios. The enhanced signals at \(m/z = 72\) (N[C₂H₅]⁺) and \(m/z = 73\) (HN[C₂H₅]⁺) during the first half cycle are consistent with the removal of the precursor ligands during precursor adsorption. However, it should be noted that these signals can also originate from the cracking of the precursor molecule in the mass spectrometer. Very small signals at these \(m/z\) values were also observed during the second half cycle whereas the signals were absent during steps in which the plasma was ignited without preceding precursor dosing. This suggests that after the first half cycle indeed a fraction of the -N(C₂H₅)₂ ligands remain intact on the surface. The latter can also be concluded from the other species observed during the second half cycle. During this plasma step, the prominent \(m/z\) ratios that were detected included \(m/z = 2\) (H⁺), \(m/z = 18\) (H₂O⁺), \(m/z = 28\) (CO⁺) and \(m/z = 44\) (CO₂⁻). Figure 9 shows the signals at \(m/z = 18\) and \(m/z = 44\). The fact that combustion products such as CO₂ are observed during the plasma step clearly indicates that some -N(C₂H₅)₂ ligands remain on the surface after precursor adsorption.

The interpretation of mass spectrometry for plasma-assisted ALD processes is more complicated than for thermal ALD as the reaction products released from the surface can react in the plasma leading to the creation of other species and fragments. The mass spectrometry data as shown in Figure 9 should therefore be interpreted with care. However, plasma-assisted ALD also allows investigation of the optical emission spectrum during the plasma step. Figure 10 shows two optical emission spectra, one for a plasma step during ALD (recorded immediately after plasma ignition) and one for a regular O₂ plasma without preceding precursor dosing step. The presence of OH and H emission (i.e., Hα, Hβ, Hγ of the Balmer series) is clearly observed.

Figure 7. High-resolution TEM image of an ALD SiO₂ film of 7.0 ± 0.3 nm thickness deposited on a H-terminated Si(100) wafer. The SiO₂ was covered by an Al₂O₃ film deposited by plasma-assisted ALD.

Figure 8. High-resolution SEM images of a high-aspect ratio trench in Si coated by 830 cycles of ALD SiO₂. The SiO₂ was deposited on top of thermal SiO₂/ALD Al₂O₃ layers for optical contrast. The depth and average width of the trench were 18.5 and 0.6 \(\mu\)m, respectively, resulting in an aspect ratio of ∼30.
for the plasma step during ALD. These excited fragments are formed in the plasma by (electron-induced) dissociation of volatile species originating from the reactor surfaces and substrate. The inset shows the transient \( \text{H}_2 \) emission during the plasma step in the ALD cycle. The increase and subsequent decrease of the signal suggests that the reaction products are formed within the first second after plasma ignition. This interpretation is consistent with the fast saturation behavior as displayed in Figure 4c. The latter served as a reference. The most prominent emission lines have been assigned. The inset shows the transient signal due to \( \text{H}_2 \) emission after the ignition of the plasma at 0 s.

![Figure 9](image_url)  
**Figure 9.** Data from quadrupole mass spectrometry (QMS) for selected mass-over-charge ratios, i.e., \( m/z = 18 \) (\( \text{H}_2\text{O}^+ \)), 44 (\( \text{CO}_2^+ \)), 72 (\( \text{N}[\text{C}_2\text{H}_5]_2^+ \)), and 73 (\( \text{HN}[\text{C}_2\text{H}_5]_2^+ \)). During the measurements the substrate temperature was 250 °C and the wall temperature was 180 °C. In the first part of the figure only the precursor is pulsed, in the second part only the plasma and in third part both the precursor and plasma are pulsed (regular ALD cycle, with extended purge times for clarity).

**Figure 10.** Optical emission spectra (OES) for the plasma step during plasma-assisted ALD and for a regular plasma step without preceding precursor dosing. The latter served as a reference. The most prominent emission lines have been assigned. The inset shows the transient signal due to \( \text{H}_2 \) emission after the ignition of the plasma at 0 s.

**Surface Passivation Properties**

Surface passivation by single layer \( \text{SiO}_2 \) — The surface passivation properties were evaluated for \( n \)-type Si wafers that were coated on both sides with \( \text{SiO}_2 \) (20–45 nm) using a deposition temperature of \( \sim 200 \) °C. The films afforded no significant surface passivation in the as-deposited state indicated by a very low effective lifetime of \( \tau_{\text{eff}} \sim 4 \) μs. Similar results were reported for plasma ALD \( \text{Al}_2\text{O}_3 \) films.\(^{39, 40}\) The as-deposited \( \text{Al}_2\text{O}_3 \) films exhibited a very high defect density at mid gap (\( \Delta D_{\text{it}} \sim 10^{14} \) eV\(^{-1}\) cm\(^{-2}\)), at least partially related to the vacuum UV (VUV) radiation present in the plasma.\(^{40}\) It is expected that VUV also plays a role in the poor passivation quality obtained for as-deposited \( \text{Al}_2\text{O}_3 \). Figure 11 shows the injection-level-dependent effective lifetime after annealing the \( \text{Al}_2\text{O}_3 \) films in forming gas (mixture of \( \sim 10\% \text{H}_2 \) in \( \text{N}_2 \)) at a temperature of \( 400 \) °C. The passivation properties improved significantly during annealing, resulting in \( \tau_{\text{eff}} \) values up to 560 μs (Δ\( \tau \text{eff} = 1 \times 10^{14} \) cm\(^{-2}\)), which correspond to \( S_{\text{eff}} < 25 \) cm/s. Nonetheless, the level of surface passivation after annealing was not stable in time and gradually deteriorated (inset Fig. 11). This transient behavior is indicative of progressively higher \( D_{\text{it}} \) values. Issues with the long term stability of the passivation by silicon oxides have been reported before for chemical oxides.\(^{41}\)

In an attempt to improve the passivation properties of ALD \( \text{SiO}_2 \), the effect of a high temperature annealing step at \( 900 \) °C (1 min) was studied. A reduction of the film thickness by \( \sim 10\% \) was observed during this annealing step and also the refractive index decreased, indicating densification of the film. However, subsequent annealing in forming gas at \( 400 \) °C did not lead to a significantly improved level of passivation or stability compared to a reference sample which did not receive the 900 °C annealing step. The results show that the level of passivation associated with ALD \( \text{SiO}_2 \) was significantly lower than obtained by thermally-grown \( \text{SiO}_2 \) for which typically \( S_{\text{eff}} \) values \( < 10 \) cm/s are obtained.

Surface passivation by \( \text{SiO}_2/\text{Al}_2\text{O}_3 \) stacks — We have recently demonstrated that the interface properties of \( \text{SiO}_2 \) films synthesized by high-rate plasma enhanced chemical vapor deposition (PECVD) could be improved dramatically by the application of an \( \text{Al}_2\text{O}_3 \) capping film and subsequent annealing.\(^{14}\) For these stacks, comprising \( \text{Al}_2\text{O}_3 \) films with a thickness down to \(~5 \) nm, very low surface recombination velocities with values of \( S_{\text{eff}} < 5 \) cm/s were achieved.\(^{14}\) Figure 11 shows the effective lifetime for a 12 nm ALD \( \text{SiO}_2/30 \) nm \( \text{Al}_2\text{O}_3 \) stack after annealing in \( \text{N}_2 \) (400 °C, 10 min). Note that in contrast to single layer \( \text{ALD SiO}_2 \), annealing in \( \text{N}_2/\text{H}_2 \) was not necessary. The high effective lifetimes up to \( \sim 7 \) ms correspond to exceptionally low \( S_{\text{eff}} \) \( < 3 \) cm/s for \( n \)-type Si.\(^{15}\) It is furthermore important to mention that the effective lifetime induced by the \( \text{SiO}_2/\text{Al}_2\text{O}_3 \) stacks remained...
virtually constant over the monitored period of several months. Preliminary results suggested that the passivation performance for p-type Si was lower than for n-type Si. Values of $S_{eq}$ $< 17$ cm/s and $< 50$ cm/s were obtained for stacks comprising SiO$_2$ with a thickness of $\sim 1$ and 12 nm, respectively, using 2 $\Omega$-$cm$ p-type c-Si substrates. This difference between n- and p-type Si may be related to the positive charges present in the stacks comprising relatively thick SiO$_2$ interlayers as will be discussed below. On p-type Si, a small positive charge density may attract the minority carrier electrons toward the surface increasing the recombination rate. 

For application in high-efficiency solar cells, it is relevant to mention that the stacks exhibited a good thermal stability during high temperature processing.\textsuperscript{14}

**Capacitance-Voltage Measurements**

Capacitance-voltage measurements were carried out to study the electronic interface properties corresponding to the ALD SiO$_2$ films and SiO$_2$/Al$_2$O$_3$ stacks. The C-V data are shown in Fig. 12, for SiO$_2$ thicknesses in the range of 1–30 nm. The measurements were performed using frequencies of 1, 10, 100 kHz. The voltage was swept from $-4$ to $4V$ to go from accumulation to inversion conditions.

### Dielectric constant.

The dielectric constant $k$ was determined from the capacitance density $C_{ox}$ of the dielectric (by the Hauser model) and the thickness information from SE, by:

$$k = \frac{d \times C_{ox}}{\varepsilon_0}$$ \hspace{1cm} [2]

with $d$ the film thickness, and $\varepsilon_0$ the vacuum permittivity. Table II gives the dielectric constants obtained for the SiO$_2$ films and the stacks after annealing at 400°C. For the thinnest film ($\sim 5$ nm), for example, a dielectric constant of $k = 4.7 \pm 0.4$ was extracted from the C-V data. The higher $k$-values obtained for ALD SiO$_2$ relative to thermally-grown SiO$_2$ ($k \sim 3.9$) can likely be attributed to the presence of residual OH groups in the material (Table I).\textsuperscript{20, 42} In comparison, Hiller et al. reported a value of $k = 6.1$ (as-deposited) and $k = 3.6$ for ALD SiO$_2$ films after annealing at 1000°C.\textsuperscript{30} For a stack comprising an ALD SiO$_2$ film of 1 nm and an Al$_2$O$_3$ layer of 30 nm, a value of $k = 8 \pm 0.4$ was determined. This value was similar (within measurement accuracy) to the value obtained for an Al$_2$O$_3$ reference film deposited directly on H-terminated Si (Table II). These values are in good agreement with those reported in the literature for single layer Al$_2$O$_3$ ($k \sim 7$–9).\textsuperscript{26, 43–45} As expected, the dielectric constants of the stacks were observed to decrease for increasing SiO$_2$ interlayer thickness due to the lower $k$-value associated with SiO$_2$.

### Capacitance-Voltage Measurements

The C-V data are shown in Fig. 12, for SiO$_2$ thicknesses in the range of 1–30 nm. The measurements were performed using frequencies of 1, 10, 100 kHz. The voltage was swept from $-4$ to $4V$ to go from accumulation to inversion conditions.

**Table II.** SiO$_2$ thickness dependent electronic properties of ALD SiO$_2$ films and ALD SiO$_2$/Al$_2$O$_3$ stacks. As a reference, the data for Al$_2$O$_3$ on Si is shown.\textsuperscript{26} The relative dielectric constant $k$, effective fixed charge density $Q_{eff}$ (Eq. 3), negative charge at SiO$_2$/Al$_2$O$_3$ interface $Q_{neg}$ (Eq. 4) and interface defect density at mid gap $D_q$ were extracted from the C-V measurements (Fig. 12). The estimated error in the dielectric constant is $\sim 0.4$; the error in $Q_{eff}$ for single layer SiO$_2$ and Al$_2$O$_3$ is estimated to be $\pm 2 \times 10^{11}$ cm$^{-2}$; the error in $D_q$ for single layer SiO$_2$ is $\sim 8.5 \times 10^{12}$ cm$^{-2}$. The error in the $D_q$ values for the stacks leads to maximum $D_q$ values of $10^{11}$ cm$^{-2}$ eV$^{-1}$. The SiO$_2$ films were annealed in H$_2$/N$_2$, while the Al$_2$O$_3$ and SiO$_2$/Al$_2$O$_3$ stacks were annealed in N$_2$.

\textsuperscript{a} Using Eq. 4, using $Q_{pos} = 8 \times 10^{11}$ cm$^{-2}$

$-\equiv$ not applicable.

**Figure 12.** Capacitance-voltage (C-V) measurements for (a) single layer ALD SiO$_2$ films after annealing in forming gas (400°C, N$_2$/H$_2$, 10 min) and (b) for SiO$_2$/Al$_2$O$_3$ stacks after annealing in N$_2$ (400°C, 10 min). The SiO$_2$ thickness was varied and the Al$_2$O$_3$ film thickness was 30 nm. The transients were measured using frequencies of 1, 10 (not shown) and 100 kHz. The C-V measurements were carried out several weeks after the annealing treatment. As substrates, 2 $\Omega$-cm p-type c-Si wafers were used.

**Fixed charges in ALD SiO$_2$.** The extraction of fixed charges from the flatband voltage shift $V_{FB}$ requires an assumption about the position of these charges. In a first approximation, it is common to assume that all charges reside at the Si/SiO$_2$ interface. The effective fixed charge density $Q_{eff}$ (expressed in cm$^{-2}$) is then simply given by the relation:

$$Q_{eff} = -(V_{FB} - \phi_{m}) \times C_{ox}$$ \hspace{1cm} [3]

with $\phi_{m}$ the work function difference between the Al contact and the p-type Si substrate, and $q$ equal to the elementary charge. For single layer ALD SiO$_2$, we observed a linear trend between $V_{FB}$ and the SiO$_2$ thickness. By extrapolation, an $y$-axis intercept of $-1.14 \pm 0.02$ eV was found which represents the value of $\phi_{m}$. Moreover, this linear relation implies that the assumption of the presence of the charges at the interface is reasonable, as charge distributed in the bulk of SiO$_2$.
a film would lead to a nonlinear thickness dependence. For ALD SiO₂, relatively small VFB values were observed with corresponding positive QF values in the range of 6–8×10¹¹ cm⁻² (Table II). The fact that no hysteresis was observed in the C-V characteristics indicates that the VFB shifts were not caused by mobile charges. The presence of positive fixed charges is well-known for SiO₂ deposited at low temperatures, and has for instance been reported for PECVD and ALD SiO₂ films. However, for PECVD SiO₂, Buchanan et al. have provided evidence that another (unknown) type of defect, also within tunneling distance (i.e. < 5 nm) of the Si substrate, is more likely to be responsible for the fixed charges. It has also been hypothesized that H may be involved in the generation of the positive charges.

Fixed charges in SiO₂/Al₂O₃ stacks.— In contrast to the single layers, large positive VFB values were observed for the SiO₂/Al₂O₃ stacks comprising thin SiO₂ interlayers (thickness of 1 and 2.5 nm) and for a single layer ALD Al₂O₃ reference sample deposited directly on H-terminated Si (Table II). These VFB values indicate the presence of a significant amount of net negative charge. When we apply the model of Eq. 3, we find a decreasing negative QF for increasing SiO₂ thickness (Table II). For the thickest SiO₂ interlayer of 30 nm, a negative VFB is found corresponding to a net positive QF of +5 × 10¹¹ cm⁻² when assuming that all charges are located at the Si/SiO₂ interface. However, the latter assumption is not realistic for the stacks. To further interpret the VFB values in terms of fixed charges, we can also consider the influence of multiple charge contributions. It is well known that the negative charges associated with Al₂O₃ are mainly located near the SiO₂/Al₂O₃ interface. The negative charges will shift away from the Si interface when using SiO₂ interlayers between Si and Al₂O₃. In addition, positive charges associated with SiO₂ need to be taken into account. The latter can also be directly appreciated from the stack with a 30 nm interlayer. Therefore, in addition to the relation given in (3), an alternative, more complex model can be introduced which accounts for a positive charge contribution Qpos at the Si/SiO₂ interface and a negative charge contribution Qneg at the SiO₂/Al₂O₃ interface.

\[
Q_{\text{pos}} = \frac{d_{\text{SiO}_2}}{\varepsilon_0\varepsilon_{\text{SiO}_2}} + (Q_{\text{neg}} + Q_{\text{eff}}) = \frac{d_{\text{Al}_2\text{O}_3}}{\varepsilon_0\varepsilon_{\text{Al}_2\text{O}_3}} - \frac{(V_{\text{FB}} - \phi_{\text{si}})}{q}
\]

For simplicity, we consider d₃₀₂ to be the nominal ALD SiO₂ thickness as determined by SE. In order to obtain an estimate of Qneg using Eq. 4, a value for Qneg of +8×10¹¹ cm⁻² may be appropriate, i.e. the value obtained for thick SiO₂ films without capping layer. In addition, in contrast to Eq. 3, we cannot use the experimentally determined values for C_{\text{Si}} in Eq. 4. Therefore, we consider k_{\text{SiO}_2} and k_{\text{Al}_2\text{O}_3} to be constant, with values of 5.5 and 8, respectively. Using these values, it is found from the analysis that Qneg decreases with increasing SiO₂ interlayer thickness from ~6×10¹² cm⁻² (no ALD SiO₂) to ~4×10¹¹ cm⁻² (30 nm SiO₂). Note that the latter value (and its polarity) should be interpreted with care as this value significantly depends on the accuracy of the substituted value for Qpos. However, as expected, models (3) and (4) lead to the same main conclusion that the negative charge density associated with Al₂O₃ is strongly reduced for thicker SiO₂ interlayers. Moreover, for sufficiently thick SiO₂ films the fixed positive charges play a more dominant role.

In general, the observations are in good agreement with a recent study by Wolf et al. using CV measurements. In addition, the results are in line with a recent study using optical second-harmonic generation (SHG) experiments. The SHG measurements are sensitive to electric fields induced in the space charge region below the Si surface caused by the fixed charges present in the passivation scheme. It was found that the induced electric field strongly decreased for increasing SiO₂ interlayers and vanished for a SiO₂ interlayer thickness of ~5 nm. However, a small net positive charge density was determined by SHG for an interlayer thickness of 12.5 nm while the C-V results suggested a small, but negative QF for this stack. These observations may be related to the fact that SHG is a fundamentally different measurement technique. For example, SHG is a non-contacting and non-intrusive technique, while the C-V measurements obviously require the application of metal contacts. The latter may influence directly or indirectly the fixed charges in the stack. For example, the exact value for \( \phi_{\text{si}} \) may slightly depend on the dielectric below (i.e. SiO₂ or Al₂O₃).

The strong dependency of Qpos on the SiO₂ thickness may point to a role of charge injection from the Si substrate in defect states at the remote SiO₂/Al₂O₃ interface during annealing. The SiO₂ interlayer could serve as a barrier for charge injection and affect the formation of negative charges accordingly. As discussed in Ref. 15, the changes in net fixed charge density and associated field-effect passivation had a significant impact on the level of passivation but also on the injection level dependence of the effective lifetime.

Interface defect density.— The interface defect density was determined from the frequency dispersion in the C-V data. The difference in the high and low frequency C-V characteristics corresponding to the ALD SiO₂ films is indicative of the presence of a significant amount of electronically active interface defects (Fig. 12a). Relatively high Dit values of ~10¹³ eV⁻¹ cm⁻² were obtained for single layer ALD SiO₂ films after forming gas annealing (Table II). This is consistent with the relatively high Sϕ values that were measured for similar samples, especially after aging (inset Fig. 11). In strong contrast, ultralow Dit values were obtained for the SiO₂/Al₂O₃ stacks, with Dit < 10¹¹ eV⁻¹ cm⁻². In addition, the data did not reveal a clear relation between Dit and the SiO₂ film thickness (1–30 nm). Therefore, the stacks induced a high level of chemical passivation regardless of SiO₂ thickness. The low defect densities can be related to the effective hydrogenation of the interface under influence of hydrogen from the Al₂O₃ capping film. During annealing, the prominent P₅-type defects (Si dangling bond) at the Si/SiO₂ interface are effectively passivated by hydrogen. From the data in Table II, it can be concluded that the use of an Al₂O₃ capping layer leads to a significantly higher interface quality than obtained by annealing the ALD SiO₂ films in forming gas.

Conclusions

A plasma-assisted ALD process for SiO₂ has been developed employing H₃Si[N(C₂H₅)₃] as Si precursor in combination with an O₂ plasma as the oxidant. It was demonstrated that the ALD process is suited for the low-temperature synthesis of high-quality SiO₂ films with the material properties being relatively insensitive to the substrate temperature in the range of 100 – 300 °C. The ALD process combined comparatively high growth rates (0.8 – 1.7 Å/cycle) with relatively short dosing and purge times. Moreover, the plasma-assisted ALD process led to good conformity for trenches with an aspect ratio of ~30, even for relatively short plasma exposure times of 4.5s.

Regarding the electronic properties, the interface defect density was relatively high (Dit ~10¹² eV⁻¹ cm⁻², after aging) for single layer ALD SiO₂. The application of an Al₂O₃ capping layer in conjunction with a low-temperature anneal led to a dramatic improvement in the interface quality with Dit < 10¹¹ eV⁻¹ cm⁻². Corresponding ultralow surface recombination velocities < 3 cm/s were measured for these stacks. The thickness of the SiO₂ interlayer was found to control the fixed charge density associated with the SiO₂/Al₂O₃ stacks. A transition from a high negative net charge density to a relatively low positive net charge density was observed.

These results may have implications for a wide range of existing and future applications in which the thickness control and
conformality of the ALD SiO₂ films are critical factors. Moreover, the ALD SiO₂ nanolayers can be applied in effective surface passivation schemes for future high-efficiency silicon solar cells.
