(Received 18 December 2008; published 12 May 2009)

We apply a hybrid molecular dynamics and mesoscopic simulation technique to study the dynamics of two-dimensional colloidal disks in confined geometries. We calculate the velocity autocorrelation functions and observe the predicted \( r^{-1} \) long-time hydrodynamic tail that characterizes unconfined fluids, as well as more complex oscillating behavior and negative tails for strongly confined geometries. Because the \( r^{-1} \) tail of the velocity autocorrelation function is cut off for longer times in finite systems, the related diffusion coefficient does not diverge but instead depends logarithmically on the overall size of the system. The Langevin equation gives a poor approximation to the velocity autocorrelation function at both short and long times.

I. INTRODUCTION

The role of hydrodynamics in two dimensions (2D) is considerably more complex than in three dimensions (3D). For example, when, in 1851, George Gabriel Stokes [1] tried to extend his famous calculation of the low Reynolds (Re) number flow field around a sphere to that of a cylinder, he found that there was no finite solution because [2]

\[
\text{the pressure of the cylinder on the fluid continually tends to increase the quantity of fluid which it carries with it, while the friction of the fluid at a distance from the cylinder continually tends to diminish it. In the case of a sphere, these two causes eventually counteract each other, and the motion becomes uniform. But in the case of a cylinder, the increase in the quantity of fluid carried continually gains on the decrease due to the friction of the surrounding fluid, and the quantity carried increases indefinitely as the cylinder moves on.}
\]

This observation was later called the “Stokes paradox.” Experimental realizations of 2D systems are, of course, always embedded in one way or another in the 3D world. In a classic set of papers, Saffman and Delbrück [3] demonstrated how taking into account the upper and lower boundaries on a 2D system solves the Stokes paradox because these boundaries open up a new channel for momentum flow out of the system. If the viscosity of the confining medium is \( \eta' \), while the viscosity of the confined medium of height \( h \) is \( \eta \), then a new length scale emerges,

\[
L_5 \sim \frac{h \eta'}{\eta},
\tag{1}
\]

beyond which the true 3D nature of the whole system needs to be taken into account. The zero Re number Stokes equations also cease to be valid at distances larger than \( L_{\text{Re}} \sim v/U \), where \( v \) is the kinematic viscosity and \( U \) is the velocity of the fluid, because inertial forces must be taken into account. Although inertial terms also become relevant at similar length scales in 3D, this fact does not need to be taken into account to obtain bounded solutions of the Stokes equations. For length scales \( L \ll \min(L_5,L_{\text{Re}}) \), the total momentum in the 2D layer is approximately conserved and Saffman showed that for a disk of radius \( R_c \) and thickness \( h \), the 2D diffusion coefficient for stick boundary conditions takes the following finite form [3]:

\[
D^{2d} = \frac{k_BT}{4\pi \eta^3} \left[ \ln \left( \frac{R_c \eta}{h \eta'} \right) - \gamma \right],
\tag{2}
\]

where \( k_B \) is Boltzmann’s constant, \( T \) is the temperature, and \( \gamma=0.5572 \) is Euler’s constant. Note that in contrast to the 3D form, where the diffusion coefficient only depends on \( k_BT/R_c \) and \( \eta \), here both the thickness of the film \( h \) and the viscosity of the boundary \( \eta' \) enter into the expression for the diffusion coefficient. Equation (1) also implies that 2D hydrodynamic behavior will be most evident when the confining boundary has a very low viscosity.

Examples of experimental systems where 2D hydrodynamics are important include diffusion of protein and lipid molecules in biological membranes [4–6], Cicuta et al. [7] recently directly measured the diffusion of liquid domains in giant unilamellar vesicles (GUVs) and found that the mean-square displacement of the domains scaled logarithmically with their radius, in agreement with Saffman’s prediction.

Experiments on colloidal particles confined in a thin sheet of fluid (such as a soap film) have used video imaging [8] and optical tweezers [9] to explicitly demonstrate that the hydrodynamic interaction between the particles decays logarithmically with distance. These effects can be understood by solving the 2D Stokes equations and carefully taking into account the boundary conditions. Because the 3D boundary in these cases is air, with a much smaller viscosity than the soap solution, \( L_5 \) can be as large as 0.1\( \text{m} \) or more. The low Re numbers typical of colloidal suspensions mean that \( L_{\text{Re}} \) can be much larger than that, on the order of many meters.

If a 2D system is confined to within dimensions \( L \ll \min(L_5,L_{\text{Re}}) \) then the diffusion coefficient scales with system size as [10]

\[
D \sim \ln(L/R_c).
\tag{3}
\]
The goal of this paper is to use computer simulations to study the hydrodynamics of colloidal discs in confined geometries. We limit ourselves to 2D, which has the advantage that simulations are faster than in 3D. The price we pay for this is that we must take into account some of the subtleties of 2D hydrodynamics described earlier, such as the finite-size effects illustrated, for example, by Eq. (3). But these effects can also be observed in experiments on quasi-two-dimensional systems and are therefore interesting in their own right.

We use a combination of stochastic rotation dynamics (SRD) [11–13] to describe the solvent and molecular dynamics (MD) to solve the equations of motion for the colloids. Such a hybrid technique was first employed by Malevanets and Kapral [14] and used to study colloidal sedimentation by ourselves [15] and by Hecht et al. [16]. We have recently completed an extensive study of this method to study the hydrodynamics of colloidal suspensions [13], which we will call ref I, and we summarize some of the main points of the method in Sec. II.

Particle-based methods such as SRD (Note that in the literature this method is also sometimes called multiple particle collision dynamics, see, e.g., [17],) have the advantage that boundary conditions are very easy to implement as external fields. This contrasts with traditional methods of computational fluid dynamics where boundary conditions are typically harder to implement. Thus methods such as SRD may be ideally suited for the study of colloids in confined geometries. The rapid development of new methods to create microfluidic systems is also stimulating experimental studies on colloids in confined geometries [18]. For that reason, computer simulation techniques that can calculate the properties of colloids in narrow channels will become increasingly important. Another field of possible application includes flow in porous media [19,20].

We proceed as follows. In Sec. II we describe the hybrid molecular dynamics/SRD method we employ and sketch out the key hydrodynamic parameters that govern the flow behavior. Section III describes simulations of a pure SRD fluid system in 2D, where we find that the effects of hydrodynamic correlations are more pronounced than those found in 3D [17]. We also explore the important role of finite-size effects. In Sec. IV we calculate the velocity autocorrelation function (VACF) for colloids in 2D and show how confinement qualitatively affects their long-time behavior. In Sec. V, we analyze the diffusion coefficient for colloids in 2D and connect the confinement effects seen for the velocity autocorrelation function to the behavior of the diffusion coefficient. We summarize our main conclusions in Sec. VI.

II. HYBRID MD-SRD COARSE-GRAINED SIMULATION METHOD

To describe the hydrodynamic behavior of colloids induced by a background fluid of much smaller constituents, some form of coarse graining is required. The hydrodynamics can be described by the Navier Stokes equations that coarse grain the fluid within a continuum description. The downside of going directly through this route is that every time the colloids move, the boundary conditions on the differential equations change, making them computationally expensive to solve.

An alternative to the direct solution of the Navier Stokes equations is to use particle-based techniques that exploit the fact that only a few conditions, such as (local) energy and momentum conservation, need to be satisfied to allow the correct (thermo) hydrodynamics to emerge in the continuum limit. Simple particle collision rules, easily amenable to efficient computer simulation, can therefore be used. Boundary conditions (such as those imposed by colloids in suspension) are easily implemented as external fields. One of the first methods to exploit these ideas was direct simulation Monte Carlo (DSMC) method of Bird [21,22]. The lattice Boltzmann (LB) technique where a linearized and preaveraged Boltzmann equation is discretized and solved on a lattice [23] is a popular modern implementation of these ideas and in particular has been extended by Ladd and others [24–29] to model colloidal suspensions.

In this paper, we implement the SRD method first derived by Malevanets and Kapral [11]. It resembles the Lowe-Anderson thermostat [30] but has the advantage that transport coefficients have been analytically calculated [12,31,32], greatly facilitating its use. It is important to remember that for all these particle-based methods, the particles should not be viewed as some kind of composite supermolecular fluid units but rather as coarse-grained Navier Stokes solvers (with noise in the case of SRD) [13].

An SRD fluid is modeled by N point particles of mass \( m \), with positions \( \mathbf{r}_i \) and velocities \( \mathbf{v}_i \). The coarse-graining procedure consists of two steps: streaming and collision. During the streaming step, the positions of the fluid particles are updated via

\[
\mathbf{r}_i(t + \delta t) = \mathbf{r}_i(t) + \mathbf{v}_i(t) \delta t.
\]

In the collision step, the particles are split up into cells with sides of length \( a_0 \), and their velocities are rotated around an angle \( \alpha \) with respect to the cell center-of-mass velocity,

\[
\mathbf{v}_i(t + \delta_c) = \mathbf{v}_i(t) + \mathbf{v}_{c.m.}(t) \mathcal{R}_i(\alpha) \mathbf{v}_i(t) - \mathbf{v}_{c.m.}(t),
\]

where \( \mathbf{v}_{c.m.} = \sum_i (m \mathbf{v}_i)/\Sigma m \) is the center-of-mass velocity of the particles the cell to which \( i \) belongs, \( \mathcal{R}_i(\alpha) \) is the cell rotational matrix, and \( \delta_c \) is the interval between collisions. The purpose of this collision step is to transfer momentum between the fluid particles while conserving the energy and momentum of each cell.

The fluid particles only interact with one another through the collision procedure. Direct interactions between the solvent particles are not taken into account, so that the algorithm scales as \( O(N) \) with particle number. This is the main cause of the efficiency of simulations using SRD. The carefully constructed rotation procedure can be viewed as a coarse graining of particle collisions over space and time. Mass, energy, and momentum are conserved locally, so that on large enough length scales the correct Navier Stokes hydrodynamics emerges, as was shown explicitly by Malevanets and Kapral [11].

An advantage of SRD is that it can easily be coupled to a solute as first shown by Malevanets and Kapral [14] and
studied in detail in a recent paper by two of the present authors [13] (ref I). If we wish to simulate the behavior of spherical colloids of mass $M$, they can be embedded in a solvent using a molecular-dynamics technique. For the colloid–colloid interaction, we use a standard steeply repulsive potential of the form,

$$
\varphi_{cc}(r) = \begin{cases} 
4\epsilon \left( \frac{\sigma_{cc}}{r} \right)^6 - \frac{\sigma_{cc}}{r} + \frac{1}{4} & (r \leq \frac{2^{1/6}\sigma_{cc}}{\sigma_{cc}}) \\
0 & (r \geq \frac{2^{1/6}\sigma_{cc}}{\sigma_{cc}}),
\end{cases}
$$

while the interaction between the colloid and the solvent is described by a similar but still steep potential,

$$
\varphi_{cs}(r) = \begin{cases} 
4\epsilon \left( \frac{\sigma_{cs}}{r} \right)^{12} - \left( \frac{\sigma_{cs}}{r} \right)^6 + \frac{1}{4} & (r \leq \frac{2^{1/6}\sigma_{cs}}{\sigma_{cs}}) \\
0 & (r \geq \frac{2^{1/6}\sigma_{cs}}{\sigma_{cs}}),
\end{cases}
$$

where $\sigma_{cc}$ and $\sigma_{cs}$ are the colloid–colloid and colloid–solvent collision diameters. We propagate the ensuing equations of motion with a velocity Verlet algorithm [33] using a molecular-dynamics time step $\Delta t$:

$$
R_i(t + \Delta t) = R_i(t) + V_i(t)\Delta t + \frac{F_i(t)}{2M}\Delta t^2,
$$

$$
V_i(t + \Delta t) = V_i(t) + \frac{F_i(t) + F_i(t + \Delta t)}{2M}\Delta t,
$$

where $R_i$ and $V_i$ are the position and velocity of the colloid, and $F_i$ is the total force exerted on the colloid. Coupling the colloids in this way leads to slip boundary conditions. Stick boundary conditions can also be implemented [34], but for qualitative behavior, we do not expect there to be important differences. In parallel, the velocities and positions of the SRD particles are streamed in the external potential given by the colloids and the external walls and updated with the SRD rotation-collision step every time step $\Delta t$. To prevent spurious depletion forces, we set the interaction range $\sigma_{cc}$ slightly below half the colloid diameter $\sigma_{cc}/2$ and include a small compensating potential for very short distances [when $\beta\varphi_{cs}(r) \geq 2.5$]. For further details of how this procedure reproduces the correct equilibrium behavior, see ref I [13].

The larger the ratio $\sigma_{cs}/a_0$, the more accurately the hydrodynamic flow fields will be reproduced. Here we use $\sigma_{cs}/a_0 = 4.3$ and $\sigma_{cs} = 2a_0$, which was shown in ref I to reproduce the flow fields with small relative errors for a single sphere in a 3D flow. Other parameters choices taken from ref I include $\epsilon_{cc} = \epsilon_{ps} = 2.5k_BT$ for the colloids and $\gamma = 5$, $\alpha = \frac{1}{2}\pi$ for the SRD particle number density and rotation angle, respectively. The time steps for the MD and SRD are set by slightly different physics [13], and we chose $\Delta t = 0.025t_0$ and $\Delta t_c = 0.1t_0$, where $t_0 = a_0/\sqrt{5\epsilon/3\kappa}$ is the unit of time in our simulations.

Coarse-graining methods such as SRD are useful when they make the calculation of certain desired physical properties more efficient. To achieve this, compromises must be made (there is no such thing as a free lunch). For colloidal suspensions, for example, the Re number is typically very low, on the order of $10^{-5}$ or less, and similarly the Mach number $Ma = U/c_s$, where $U$ is a typical system velocity and $c_s$ is the velocity of sound, can be as small as $10^{-10}$. To achieve this in a particle-based simulation is extremely expensive. Resolving sound waves would mean that since they travel much faster than colloidal particles, extremely small time steps would be necessary in the simulation. Luckily even for $Ma$ numbers as high 0.1, the hydrodynamics can be accurately approximated by incompressible hydrodynamics, so that one does not need to fulfill the physical condition to obtain essentially the same physical behavior. Similarly, for many applications, as long as the Re number is significantly lower than 1, the system can still be accurately described by the Stokes equations. A more detailed discussion of these length scales and hydrodynamic numbers can be found in ref I, and we will implicitly be making use of these arguments for the current work.

A similar set of arguments can be made for the time scales of a real colloidal fluid compared to those found in our coarse-grained description. For example, the kinematic time defined as $\tau_{ki} = \sigma_{cc}^2/\nu$, i.e., the time it takes a the vorticity to diffuse one colloid radius, is on the order of $10^{-6}$ s for a buoyant colloid of radius $1$ $\mu$m suspended in water. For the same system, the diffusion time $\tau_{D} = \sigma_{cc}^2/D = 5$ s. Resolving these time scales in one simulation would be very inefficient. In ref I, we claim that successful coarse-graining techniques must telescope down the hierarchy of time scales to more manageable separations that are efficient for computational purposes. We argue that what is needed is not an exact representation of all the time scales of the physical system but rather a clear time-scale separation. For example, having $\tau_D$ be only 1 or 2 orders of magnitude smaller than $\tau_0$ can still lead to an accurate description of the desired physics. However, interpreting the results means taking this telescoping down of time scales into account and to do this properly, one has keep careful track of the physics involved. Expressing results as much as possible in terms of dimensionless units can facilitate this process [13].

III. DYNAMICS OF SOLVENT PARTICLES

Before investigating the behavior of colloids in suspension, we study a simpler problem of an SRD fluid confined to two dimensions. Much of this section will follow on an earlier comprehensive study by Ripoll et al. [17] in 3D, but here we focus on 2D.

We begin by deriving an expression for the velocity autocorrelation function of the SRD particles, following similar steps to those found in Ref. 17 for 3D. The $n$th collision step of the SRD method can be rewritten as

$$
v_i(t_n\Delta t_c) = v_i((n-1)\Delta t_c) + \left[ R_i(\alpha) - I \right] \times \{ v_i((n-1)\Delta t_c) - v_{c.m.}(t_n - 1)\Delta t_c) \},
$$

where $I$ is the unit matrix, and $t_n = n\Delta t_c$ is the discretized time, with $n$ as the number of collision steps, $\Delta t_c$ as the collision interval, and $v_{c.m.}$ as the cell center-of-mass velocity. The rotation matrix is defined in two dimensions as

$$
R_c(\alpha) = \begin{pmatrix} \cos \alpha & \pm \sin \alpha \\ \pm \sin \alpha & \cos \alpha \end{pmatrix}
$$

such that the rotational average over any vector $A$ becomes
\[
\langle [R(\mathbf{r}) - T]\mathbf{A} \rangle = -(1 - \cos \alpha) \langle \mathbf{A} \rangle = -\xi_\alpha \langle \mathbf{A} \rangle. \tag{9}
\]

If we now assume density fluctuations in each cell to be small, we can write \(\langle \mathbf{v}_{c,m}(n \mathbf{\delta}_t) \rangle = \frac{1}{m} \langle \sum j^n \mathbf{v}_j \rangle\). By multiplying each side by \(\langle \mathbf{v}_j(0) \rangle\) and further assuming the velocity of colliding particles to be uncorrelated, we arrive at

\[
\langle \mathbf{v}_{c,m}(n \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle = \frac{1}{m \gamma} \langle \mathbf{v}_i(0) \rangle (n \mathbf{\delta}_t) \mathbf{v}_i(0), \tag{10}\]

where \(\gamma\) is the average number of solvent particles per cell. Substituting Eqs. (10) and (9) into Eq. (8) and rearranging, we obtain an expression for the correlation of a fluid particle

\[
\langle \mathbf{v}_i(n \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle = (1 - \xi \epsilon_m) \langle \mathbf{v}_i((n - 1) \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle, \tag{11}\]

where \(\epsilon_m = 1 - \frac{1}{m \gamma}\). This expression shows that we can write the correlation at a certain time step in terms of the previous time step, from which we find that the normalized VACF is

\[
\frac{\langle \mathbf{v}_i(n \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle}{\langle \mathbf{v}_i(0) \rangle} = \epsilon^n, \tag{12}\]

where \(\xi = 1 - \xi \epsilon_m\) is the decorrelation factor. The VACF, for reasons that will become apparent later, is the quantity of interest here and has the form

\[
\langle \mathbf{v}_i(n \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle = \frac{k_B T}{m} \xi^n. \tag{13}\]

A similar analysis can be performed for the case of a single heavy tracer particle of mass \(m'\) embedded in a solvent \([17]\). The total mass in a collision box is then \((m' + m \gamma)\) such that the center-of-mass correlation is written as

\[
\langle \mathbf{v}_{c,m}(n \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle = \frac{m'}{m \gamma + m'} \langle \mathbf{v}_i(n \mathbf{\delta}_t) \mathbf{v}_i(0) \rangle. \tag{14}\]

By substituting Eq. (14) into Eq. (8), the decorrelation factor for a heavy tracer particle is found to be

\[
\xi = 1 - \xi \epsilon_m = \frac{m \gamma}{m \gamma + m'} = 1 - \xi \epsilon_m. \tag{15}\]

The self-diffusion constant \(D\) of a particle \(i\) is related to its mean-square displacement via the Einstein relation \([35]\)

\[
D = \lim_{t \rightarrow \infty} \frac{1}{4t}\langle [\mathbf{r}_i(t) - \mathbf{r}_i(0)]^2 \rangle. \tag{16}\]

The position of a particle can be written explicitly in terms of discrete time steps

\[
\mathbf{r}_i(t) = \mathbf{r}_i(0) + \sum_{k=0}^{n-1} \mathbf{v}_i(k \mathbf{\delta}_t), \tag{17}\]

so that

\[
\langle [\mathbf{r}_i(t) - \mathbf{r}_i(0)]^2 \rangle = \sum_{j=0}^{n-1} \langle \mathbf{v}_i(j \mathbf{\delta}_t) \mathbf{v}_i(k \mathbf{\delta}_t) \rangle. \tag{18}\]

We note that combining the equation above with Eq. (16) leads to the discrete form of the standard Green-Kubo expressions for the diffusion coefficient as an integral over the velocity autocorrelation function. Manipulating the sums, we find

\[
\sum_{j=0}^{n-1} \langle \mathbf{v}_i(j \mathbf{\delta}_t) \mathbf{v}_i(k \mathbf{\delta}_t) \rangle = \sum_{j=0}^{n-1} \langle \mathbf{v}_i^2(j \mathbf{\delta}_t) \rangle + 2 \sum_{j=0}^{n-2} \sum_{k=j+1}^{n-1} \langle \mathbf{v}_i(j \mathbf{\delta}_t) \mathbf{v}_i(k \mathbf{\delta}_t) \rangle = 2n \frac{k_B T}{m} \sum_{j=1}^{n-1} \langle \mathbf{v}_i(0) \mathbf{v}_i((n-j) \mathbf{\delta}_t) \rangle. \tag{19}\]

Substituting the expression for the VACF derived earlier Eq. (13) into Eq. (19), we can write the diffusion coefficient in terms of its decorrelation factor \(\xi\),

\[
D = \lim_{n \rightarrow \infty} \frac{k_B T}{m} \xi^n \left[ \frac{1}{2} + \frac{1}{n} \sum_{j=0}^{n-1} \xi^{n-j} \right] = \frac{k_B T \xi}{2m} \left[ \frac{1 + \xi}{1 - \xi} \right]. \tag{20}\]

Substituting Eq. (15) into Eq. (20) results in the following dimensionless expressions for the self-diffusion constant of a fluid and heavy tracer particle, respectively:

\[
\frac{D_{0m}}{D_0} = \lambda \left[ \frac{1}{1 - \cos \alpha} \left( \frac{m \gamma}{m' \gamma - 1} \right) - 1 \right], \tag{21}\]

\[
\frac{D_{0m'}}{D_0} = \lambda \left[ \frac{1}{1 - \cos \alpha} \left( \frac{\gamma + m'}{m} \right) - 1 \right]. \tag{22}\]

\(D_0\) denotes the unit of diffusion and is expressed as \(a_0^2 / t_0\) and \(\lambda\) is the dimensionless mean-free path. It is a measure of the average distance the fluid particles travel in between collisions and has the form \([13]\)

\[
\lambda = \frac{\mathbf{\delta}_t}{a_0} \sqrt{\frac{k_B T}{m}} = \frac{\mathbf{\delta}_t}{t_0}. \tag{23}\]

These expressions for \(D\) make a key approximation, namely, that collisions are always random and that the particle velocities are uncorrelated. This neglects any hydrodynamic effects. These expressions are thus expected to become more accurate if the mean-free path \(\lambda\) becomes larger so that the random collision approximation is a better description. Ripoll et al. \([17]\) showed that in 3D, for their simulation parameters, the expression (21) for the self-diffusion of an SRD particle began to show significant deviations from measured values when the mean-free path was smaller than 0.6. Similarly, they found that for smaller mean-free paths \(\lambda = 0.1\), these expressions could underestimate the diffusion coefficient of a tagged heavier particle of mass \(M\) by as much as 75% for \(M \approx 10m\).

In Fig. 1 we analyze the self-diffusion coefficient of a tagged SRD particle as a function of mass and of mean-free path for a square geometry with plates \(L = 32a_0\) SRD cell widths wide. Similarly to Ripoll et al. \([17]\), we find deviations due to hydrodynamics, but in 2D these are much more
pronounced. For example, as the mass increases, the hydrodynamic corrections to Eq. (21) saturate at a deviation of over 200% for larger masses. For small mean-free path, there are deviations due to hydrodynamic correlations, as shown by Ripoll et al. [17]. We observe larger deviations as a function of mean-free path than found in 3D, suggesting that for these parameters, the hydrodynamic corrections are more important in 2D than in 3D.

In contrast to the 3D results, for which finite-size effects are not very strong, we expect that in 2D the effect of box size will be much more pronounced. To illustrate this, we carried out simulations in a much larger square box of width $L=256a_0$ box sizes, now with periodic boundary conditions. These are shown in the top two plots of Fig. 2. We observe that the temporal diffusion coefficient defined as

$$D(t) = \int_0^t \langle v(t')v(0) \rangle dt'$$

continues to grow with time in a manner consistent with the expected scaling $D \sim \ln[t]$, as illustrated in the second top plot in Fig. 2. We expect the diffusion coefficient to eventually saturate for this finite box size. But for an infinite box, we expect that $D(t)$ will continue to grow indefinitely, a manifestation of the Stokes paradox. Although the SRD particles are point particles, the SRD collision box length $a_0$ does provide a second intrinsic length scale and so fixed box of fixed size $L^2$, we expect that $D \sim L/a_0$ [10]. Such a scaling is indeed observed in the bottom panel in Fig. 2. For SRD particles then, the hydrodynamic contribution to the diffusion coefficient shows similar scaling to that predicted for colloidal particles.

**IV. VELOCITY AUTOCORRELATION FUNCTIONS OF COLLOIDAL PARTICLES**

Having worked out some properties of diffusing SRD particles, we now turn to the properties of colloidal particles embedded in a solvent. If memory effects are ignored in a simple Langevin equation description of a spherical colloid of mass $M$ then the VACF of a colloidal particle can be calculated to be [37]

$$\langle v(t)v(0) \rangle = \frac{k_B T}{M} \exp(-t/\tau),$$

where the time $\tau=M/k_B T_M$ indicates how quickly particles forget their initial velocity. Its integral is related to the diffusion coefficient through the Einstein relation,

$$D = \int_0^\infty \langle v(t)v(0) \rangle dt = \frac{k_B T}{\tau}.$$  

The Einstein relation is of course valid for any physical description of the VACF.

Langevin approaches have traditionally been used for colloidal systems when hydrodynamics could be ignored. However, it is well known that hydrodynamic effects can have an important qualitative effect on the VACF. In their pioneering work, Alder and Wainwright [38] used MD simulations to demonstrate that the VACF $C(t)$ of a tagged particle exhibi-
its an algebraic decay at long times of the form \( t^{-d/2} \), instead of the exponential form predicted by the Langevin equation. They showed that this behavior was a consequence of momentum conservation and therefore quite general. For colloidal particles in 3D, the diffusion coefficient is dominated by the exponential form predicted by the Langevin equation.

For the two simulated VACFs are very close to each other for smaller times.

At times shorter than the kinematic time, there is a contribution to the overall diffusion that comes from the local random collisions between the colloid and the solvent particles. This is typically dominant on time scales less than the sonic time \( t_s = v_s/\sigma_{cs}^2 \) over which collective modes can be generated [13]. We can calculate it using standard Enskog kinetic theory, and the ensuing Enskog friction coefficient \( \xi_E \) has the following form [39]

\[
\xi_{E} = \frac{3\sqrt{2}}{4} \sigma_{cs}^2 \gamma^{3/2} \left( \frac{k_B T m M}{m + M} \right)^{1/2}
\]

in two dimensions. Thus for very short times, the decay of the VACF is characterized by the Enskog time \( t_E = M/\xi_E \) and it follows that

\[
\langle v(t)v(0) \rangle = \frac{k_B T}{M} \exp(-t/t_E)
\]

because the collisions are essentially random.

As shown in Fig. 4, for short times, on the order of the Enskog time \( t_E \), the autocorrelation function shows clear exponential decay, in good agreement with Eq. (30). The simulations shown are for two box sizes, and for short times, the VACFs are independent of system size, as expected from the Enskog theory.

At longer times, Fig. 4 clearly shows the beginning of the long-time tail. The theoretical line we plot is from Eq. (27) whilst the dotted line and the solid line denote the Langevin decay with the friction \( \xi \) for the two respective box sizes. Although the two simulated VACFs are very close to each other for smaller times, the long-time tails should all scale as \( t^{-1} \) power for the tail in 2D. That this should cause problems for the definition of the two simulated VACFs are very close to each other for smaller times.

estimates the VACF for colloids. A more in depth examination of this point can be found in Appendix B of ref I. In addition, in two dimensions, the Langevin equation (25) would predict an exponential form with different $t_\parallel$ for different box sizes because the diffusion coefficient changes with box size. By contrast, our results show that for short times the VACF is independent of box size. Clearly the Langevin equation does a poor job in capturing details of the colloidal VACF.

It is also interesting to see what happens to the VACF when the confinement is more pronounced. In confined geometries, the particle-induced flow fields should feel the presence of the walls. Bocquet and Barrat [40] showed that a sink in the decay of the long-time tails should occur after an observation time on the order of $t_\parallel = \frac{L^2}{4\eta} = \chi_s^2 t_\nu$. This time is characteristic of the time required for the long-time tail to feel the effect of the wall, when $L/2$ is the average distance to the wall. We illustrate the effect of the wall on the VACF in Fig. 5 for three different box sizes. For the two narrower boxes, the VACF clearly begins to drop below the $t^{-1}$ power law but for the largest box, of size $L = 500a_0$, we do not observe any deviation within our error bars. The sink in the tail for the $\chi_s = 8$ simulation run begins at an observation time less than $10t_\nu$, whereas the kinematic wall time in this instance is $t_{w} = 64 t_\nu$. This may be because of other wall effects that kick in earlier for such a narrow box or it may be that the cutoff in the algebraic decay is gradual and commences sooner than predicted by Bocquet and Barrat.

In an important study, Hagen et al. [41] used lattice Boltzmann simulations to investigate the VACF of a colloidal particle between rigid walls and found qualitative deviations from the standard long-time tails. In particular, for a sphere in a narrow enough cylinder, they found negative tails for the VACF $C_s(t)$ parallel to the walls that exhibited an algebraic decay such as $C_s(t) \sim t^{-3/2}$. Similarly, for a two-dimensional disk between two plates they found $C_s(t) \sim t^{-3/2}$ and for a

![Fig. 5. Log-log plot of the VACF for a colloidal particle in boxes of size $L=32, 48, 500a_0$ ($\chi_s = 8, 12, 125$). The dashed line is from Eq. (27) and shows the expected $t^{-1}$ tail. The measured VACFs deviate from this simple algebraic decay for larger times, the larger the box, the later the deviation sets in.](image)

![Fig. 6. Normalized velocity autocorrelation function of a colloidal particle confined between two walls for increasing values of $\chi_s = L/2\sigma_y$. Simulations here were performed for pipe widths $L = 8, 10, 12, 24a_0$. The different plots denote the components of the normalized VACF parallel $C_x(t)$ (top) and perpendicular $C_y(t)$ (bottom) to the walls. Note that all plots are scaled with the kinematic time $t_s = \sigma^2 c_s/\nu$ and the time scale for momentum to diffuse the distance between the walls $T_w = L^2/4\nu$. The minimum of the negative tails observed for $C_y(t)$ scale on top of each other when time is scaled with the sonic time $t_\nu = t_{W}$. The minimum of the negative tails lies in the existence of velocity gradients near the wall.](image)
which can reflect off the wall and come back a time later to push the particle in the opposite direction. This effect should become more pronounced for stronger confinement, as we observe. To check this mechanism, we note that the walls introduce another length scale $t_w = \frac{L^2}{v_d}$, which is the time it takes vorticity to diffuse to the walls. If this reflection mechanism is at play, we would expect the period of the oscillations to reflect this time scale. In the bottom right panel of Fig. 6, we observe that when $C_y(t)$ is scaled with the time $t/t_w$, the oscillation minima indeed fall on top of each other, at least for sufficiently strong confinement.

As discussed by Hagen et al. [41], the $C_y(t)$ should exhibit a negative tail that scales as $t^{-3/2}$ for sufficiently strong confinement. In the upper plot of Fig. 7, we indeed observe that the exponent is greater than $-1$ and consistent with $t^{-3/2}$, as expected, although our data is not clean enough to confirm the exact exponent. Similarly, the final decay of the component $C_x(t)$ appears closer to $t^{-1}$ than to $t^{-3/2}$.

Clearly confinement has an important effect on the long-time behavior of the VACF, and there may be further subtle effects that we have not yet been uncovered. It would be interesting, for example, to see how the angular-correlation functions, studied in Ref. [34] with SRD for 3D stick boundary colloids in the bulk phase, would behave under confinement. However, for the calculation of long-time tails, methods such as lattice Boltzmann techniques used by Hagen et al. [41], where noise does not play a big role, may be simpler and faster to use.

V. DIFFUSION COEFFICIENT OF COLLOIDAL PARTICLES UNDER CONFINEMENT

The Einstein relation (26) directly relates the VACF and the diffusion coefficient. We found that for short times, the VACF was well described by an Enskog form (30) that was largely independent of the boundaries and that at longer times it exhibited a long-time tail that was much more sensitive to the boundaries. For strong confinement, the tail could even be negative or oscillatory, but for weak confinement, it appears to scale as $C(t) \sim t^{-1}$.

For an unbounded 2D system, the diffusion coefficient does not converge, instead its behavior with time can be approximated as

$$D^{2D}(t) = \int_0^t \langle v(t)v(0) \rangle dt = \frac{k_B T}{M} \left[ \int_0^t \exp(-t/t_E)dt \right] + \int_{t_E}^t \frac{k_B T}{8\pi\nu} dt + \frac{k_B T}{8\pi\nu} \ln(t/t_E),$$

where we have assumed that the Enskog and hydrodynamic contributions to the VACF can be separated (this is not quite true) and, moreover, that the hydrodynamic tail does not kick until a time scale on the order of the kinematic time $t_k$. We also assume that $D \propto \nu$.

A. Simulations in the “bulk”

In Fig. 8, we present the temporal evolution of the self-diffusion coefficient of a colloid for a large box. We approximated colloids in the bulk by using a box of size $L^2 = 256a_0 \times 256a_0$ with periodic boundary conditions. The plot shows results for solvent densities $\gamma = 5, 10, 50$. On the time scales of the simulation, we observe behavior consistent with $D \sim \ln(t)$, as expected from the $t^{-1}$ tail of the VACF. In practice this would mean that $D$ would grow indefinitely with time and be unbounded, which is a manifestation of the Stokes paradox.
Whilst in the case of the solid line the plate separation is 64
should scale with the log of the ratio of its radius to the pipe
which indicates that the diffusion of a particle in confinement
