Droplet epitaxy (DE) is a growth method which can create III-V quantum dots (QDs) whose optoelectronic properties can be accurately controlled through the crystallisation conditions. In this work, GaAs/AlGaAs DE-QDs have been analyzed with the complimentary techniques of cross-sectional scanning tunneling microscopy and atom probe tomography. Structural details and a quantitative chemical analysis of QDs of different sizes are obtained. Most QDs were found to be pure GaAs, while a small proportion exhibited high intermixing caused by a local etching process. Large QDs with a high aspect ratio were observed to have an Al-rich crown above the GaAs QD. This structure is attributed to differences in mobility of the cations during the capping phase of the DE growth. © 2014 AIP Publishing LLC. [<http://dx.doi.org/10.1063/1.4897006>]

Solid-state quantum dots (QDs) are nanostructures which have attracted strong interest for a number of technologies such as light-emitting diodes, lasers, and solar cells. With dimensions on the order of tens of nm, excitons are spatially confined within a QD; the resultant quantum mechanical properties are determined by their morphology such as the size, shape, or composition. Traditionally QDs are grown using the Stranski-Krastanov growth mode, which takes advantage of the lattice mismatch present between different materials in a heterostructure.¹ The morphology of the QDs obtained by this process is defined by strain relaxation and surface energetics. Consequently, an abrupt change of the QD morphology from one shape to another is observed, for example, from a pyramid to a dome.² More recently, another approach to the fabrication of QDs has been developed, the so-called droplet epitaxy (DE) method.³ This technique is based on the crystallisation of a metallic group-III droplet under a flux of elements from group-V. It has been demonstrated that thermally activated, kinetically driven mass transport processes play a major role in DE.⁴ As a result, the geometrical profile of these DE-QDs can be tuned continuously and accurately by adjusting only the crystallisation conditions.⁵

While the DE growth technique can be applied to most III-V semiconductor systems, strain free GaAs/AlGaAs heterostructures offer a particular advantage by having a strong relation between their morphology and optoelectronic properties. In particular, the systematic study of GaAs/AlGaAs DE nanostructures as a function of various growth parameters has improved understanding of the kinetics of the crystallisation of the material which diffuses out of the initial Ga droplet.⁶ Knowledge about the crystallisation process and the effect of capping on the structural properties remains limited due to the lack of *in-situ* characterisation techniques. Using atomic-scale microscopy, in this paper, we present insights into the structural and chemical analysis of GaAs/AlGaAs DE-QDs. The QD chemical composition, size, and shape, in addition to being a principle factor which control

the final optoelectronic properties of a QD, also reflect the crystallisation process during the QD creation. To this end, cross-sectional scanning tunneling microscopy (X-STM) and atom probe tomography (APT)⁷ measurements have been performed.

A single multilayer sample composed of four GaAs/AlGaAs QD layers was grown on a GaAs (001) substrate by DE in a molecular beam epitaxy system. These four layers each have different initial volumes of Ga deposited to form the metallic droplets. Following the growth of an initial 100 nm Al_{0.33}Ga_{0.66}As buffer layer, DE was performed a procedure which consists of (i) Ga droplet formation, (ii) crystallization into GaAs, and (iii) capping by AlGaAs. The Ga droplets were deposited using a supply of Ga without As flux (background As pressure less than 1×10^{-7} Pa). The Ga droplets were created by depositing either 1.5, 2, 3, or 5 monolayers (ML) of Ga at 200 °C in the respective layers. The crystallization was performed under a supply of As₄ with a beam equivalent pressure of 0.033 Pa at 200 °C. In order to produce highly luminescent QDs, an uncapped annealing at 400 °C is performed *in-situ* after the crystallisation of each QD layer.⁸ Additionally, a post-growth rapid thermal annealing (RTA) at 750 °C for 4 min is performed *in-situ* after the completion of the full structure.^{9,10} As a result, the capped QDs investigated in these experiments are in their final, functional state.

The capped QDs were investigated by X-STM performed at room temperature under UHV conditions (7×10^{-9} Pa). Prior to measurement, the specimen was thinned by mechanical polishing to a thickness of approximately 0.12 mm. It was then cleaved *in-situ* in the STM presenting a clean and atomically flat (110) or (1 $\bar{1}$ 0) surface for analysis. Electrochemically etched W tips were used as probes. The STM was operated with an applied voltage bias of -2.5 V at 50 pA in constant current mode.

The specimens for APT measurement were prepared using standard dual-beam focused ion beam techniques. The 400 nm GaAs buffer layer on top of the AlGaAs region of

interest meant that an additional protective cap, other than an ion-beam deposited Pt layer, was not necessary for processing. The orientation of the lifted-out lamella relative to the crystalline axes of the wafer was tracked during the lift-out process. APT data were acquired using a CAMECA LEAP 4000X with a straight flight path of length of 90 mm. The sample temperature was 50 K. Field evaporation of ions was initiated with the assistance of a 355 nm laser, which pulsed with a frequency of 250 kHz. Each pulse had a duration of about 10 ps and delivered an energy of 1 pJ. The specimen voltage was adjusted so that, on average, for every 1000 laser pulses, three ions would be detected. With these conditions, the measured group-III to group-V element ratio was found to be close to stoichiometry, with As accounting for 49% of the detected ions.

The structures observed by X-STM and APT can be described as comprising of three principle regions: (i) the AlGaAs matrix, (ii) the Ga-rich QDs, and (iii) Al-rich (Ga-depleted) crowns, see Fig. 1(d). The structure of QDs and the Al-rich crowns will be considered separately.

FIG. 1. X-STM filled states topography images of DE-QDs. Under the X-STM imaging conditions, Al atoms give dark local electronic contrast compared to the Ga atoms. (a) 17 nm $\times$ 56 nm image of a DE-QD grown with 1.5 ML of deposited Ga. (b) Low and (c) high level of Al intermixing in 32 nm $\times$ 76 nm images of DE-QDs grown under the exact same conditions with 3 ML of deposited Ga. The dotted line indicates roughly the bottom interface of the QD. (d) 32 nm $\times$ 76 nm image of a DE-QD grown from 5 ML of deposited Ga. Labeled are (i) the AlGaAs matrix, (ii) the Ga-rich QD, and (iii) Al-rich (Ga-depleted) crown.

The geometrical profile of the GaAs/AlGaAs DE-QDs varies continuously as a function of the growth parameters. Increasing the volume of Ga deposited for the formation of metallic droplets results in QDs with higher aspect (height-to-base length) ratio. This smooth evolution of the morphology is made possible by the stepped nature of their side-facets which are typically considered to be abrupt.

About 90% of the GaAs/AlGaAs DE-QDs exhibit a low level of Al intermixing as shown in the STM topography images in Figs. 1(a), 1(b), and 1(d). Under the X-STM imaging conditions, Al atoms give dark local electronic contrast compared to the Ga atoms as can be seen in the Al_{x=0.33}Ga_{1-x}As matrix. Because the GaAs/AlGaAs system is strain-free, the Al concentration inside each GaAs QD could not be estimated by the strain relaxation method otherwise used for most strained III-V heterostructures.¹¹ Instead, as in a previous study,¹² the fraction of Al atoms in the QDs can be estimated by counting the atoms in the surface layer directly on the X-STM image. This method found that the Al fraction, x , could have values between 0.0 and 0.1, varying from one QD to the other.

However, this counting method is limited by the fact that each atom must be individually resolved. Above a concentration of $x \sim 0.2$, the disorder becomes too great and the contrast becomes too low to make an accurate estimate. As a result, the Al fraction in the AlGaAs matrix cannot be determined by X-STM. In contrast, compositional measurements by APT find that $x = 0.31 \pm 0.02$, in agreement with the expected value of $x = 0.33$ from growth calibrations.

APT data of a QD grown from 3 ML of Ga provide a quantitative, spatially resolved chemical analysis of the specimen. Figure 2(a) shows a side view (left) and a top view (right) of a single QD by means of isosurfaces indicating the (A-grey) Al fraction $x = 0.55$ and (B-yellow) Ga fraction $1 - x = 0.9$. The morphology of the QD is clearly defined by isosurface B. The elongation along the $[1\bar{1}0]$ axis and the anisotropy previously revealed by the scanning probe techniques are clearly visible. The chemical composition of the QD can be determined from a composition profile along the $[001]$ growth direction shown in Fig. 3. In agreement with the X-STM data, APT finds the QD core to be pure GaAs.

A low level of intermixing is observed at most of the QD interfaces in either the X-STM or APT data. This low level of intermixing is consistent with the small inter-diffusion coefficient between GaAs and AlGaAs reported for annealing temperatures of up to 750 °C (Ref. 13) as were used for our sample. The inter-diffusion might, however, be slightly enhanced¹⁴ for structures like our QDs that are grown at low temperature, due to the creation of point defects, like vacancies, that will mediate the diffusion of cations.¹⁵ Because the inter-diffusion is spatially limited to the QD interfaces, the pure GaAs core composition of large QDs is not affected.

In the STM images, the bottom interface of these DE-QDs is generally more broadened than the upper facets, and, as reported in an earlier study,¹² local GaAs intrusions are often present beneath. The depth of these intrusions clearly ranges from one bilayer (0.56 nm) to a few nanometers and are non-homogeneously distributed in the plane. In the STM data, a full spatial correlation was found between the

FIG. 2. (a) Side (left) and top (right) views of a single QD measured by APT. Isosurfaces contain volumes where Al fraction $x \geq 0.55$ (grey) and Ga fraction $1 - x \geq 0.9$ (yellow). The 10 nm scale bar applies to both views. (b) and (c) 2D concentration profiles of a $60 \text{ nm} \times 30 \text{ nm}$ area sampled with a 2 nm depth show the Al fraction, x , through the QD along the two orthogonal directions. The color scale goes from Al fraction $x < 0.15$ (yellow) to $x > 0.7$ (black).

presence of an intrusion and the presence of Al in the otherwise pure GaAs QD. All the strongly intermixed QDs, like the one in Fig. 1(c), show intrusion into the underlying epilayer. The presence of intrusions below the position of the metallic droplet has been reported in systems where, like in

FIG. 3. 1D composition profile of a QD obtained from the APT data. The profile was created using a 15 nm diameter cylinder positioned to intersect with the centre of the QD. The cylinder was aligned in the [001] growth direction and sampled in 1 nm bins. The relative compositions of Al and Ga are shown, along with the bulk composition of a volume of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ matrix located between the QD layers.

DE, a liquid metallic droplet (In, Ga) is formed on an arsenide semiconductor surface.¹⁶ Hence, several models have been developed which account for this so-called “drilling” or “etching” effect.¹⁷ The mechanisms suggested for this drilling effect partially explains the diversity of the nanostructures obtained by DE.^{18,19}

Whilst most of the DE-QDs present a low degree of Al intermixing, a small number of QDs ($\sim 10\%$) were observed to contain a very high concentration of Al, as shown in Fig. 1(c). By visual inspection, the Al fraction of these QDs is less than the matrix ($x = 0.3$), but is higher than the X-STM counting limit of $x < 0.2$. Due to their scarcity, none of these types of QDs were imaged in the APT measurements. These highly intermixed QDs all have a high aspect ratio and there is no pure GaAs region; that is, Al is distributed throughout the QD. Another recurring peculiarity of these highly intermixed QDs is the shifted position of their bottom interface, which is found up to a few nanometers below the nominal position as indicated by the white dotted line in Fig. 1(c).

Similarly to the mechanism for the small GaAs intrusions, a drilling effect is held responsible for both the shifted interface and the high concentration of Al in these large QDs. The main process driving the etching is the dissolution of As atoms from the substrate and their diffusion into the metal droplet. As a result, an As concentration gradient forms inside the metal droplet. In the system presented here, the As atoms diffuse towards the liquid/vapor interface, after which they either escape in the vacuum or lead to crystallisation into GaAs at the interface. This results in the liquefaction of the substrate locally below the Ga droplet. This local etching of the substrate starts with the formation of the Ga droplet and proceeds until it is completely consumed. For this reason, a low As background favors the drilling.²⁰ If the environment stays completely As free, the final structure is a hole inside the substrate surrounded by a GaAs ring. If the droplet is rapidly subjected to a high As flux, which occurs in the DE process, the As gradient is reduced. The metal droplet turns into a shallower GaAs QD with relatively small GaAs intrusions in the substrate.

This model explains well why large intrusions and a strong Al intermixing are more frequently found for the largest QDs grown from 5 and 3 ML of deposited Ga. At constant As flux, the crystallisation of large droplets requires a longer time, leading to a stronger etching of the surface. Additionally, the As gradient, which is the driving force, is strongest in QDs with higher aspect ratios. As a result, the substrate is heavily etched below the whole QD and the diffusion of Al in the QD is hereby strongly promoted. Considering that Al is present throughout these types of QDs, the diffusion must have taken place before the complete crystallisation of the liquid droplet.

An Al-rich (Ga-depleted) crown is another structural feature associated with the GaAs/AlGaAs DE-QDs which is revealed by X-STM and APT analysis, presented in Figs. 1 and 2. The color scale of the APT derived 2D concentration maps in Figs. 2(b) and 2(c) goes from Al fraction $x < 0.15$ (yellow) to $x > 0.7$ (black). This local Al enrichment is found above 70% of the larger QDs (grown from 3 and 5 ML of Ga drops). Very rarely (less than 5% of cases), QDs grown from 2 ML of Ga deposited show such a feature. QDs grown from

1.5 ML of Ga do not exhibit any local Al enrichment. As clearly displayed in Figs. 1 and 2(a), only the upper part of the QD is covered by this crown. Moreover, the 3D and 2D APT representations of the QD shows that the shape of this Al-rich region shape is anisotropic. The crown has a chevron (inverted-v) shape along the major axis of the QD. The magnitude of this enrichment in Al above the QD can be estimated quantitatively from the composition profile along the [001] growth direction shown in Fig. 3 and by measuring the bulk composition inside the isosurface shown in Fig. 2(a). The average Al fraction is $x=0.67$ inside the $x \geq 0.55$ isosurface.

A mechanism based on the difference in Ga and Al adatom mobility is suggested to explain the enrichment of Al (depletion of Ga) above high aspect ratio QDs. The thermodynamically stable configuration of GaAs on AlGaAs is a 2D layer due to the high solid–solid surface tension and the lack of strain. However, the high aspect ratio of the QD nanostructures increases the surface tension at the apex and confers a curvature to the growth front right on top of the QDs. This geometrical condition results in the diffusion of Al and Ga adatoms along the side facets during capping. Because Ga atoms are more mobile than Al atoms,²¹ Ga atoms will be more likely to diffuse away from QD top, while, comparatively, the Al atoms will not travel as far. In this way, the AlGaAs layer crystallised on top of the QD remains rich in Al.

Additionally, the difference in migration may also vary depending on the side facets. This mechanism explains well the highly localized position of this feature at the top of the QDs and its anisotropy. Furthermore, because this separation process continues until the growth front has flattened out, the Ga-depleted regions extend notably along the [001] direction, leading to the observed residual Al-enrichment above the crown. Additional crystallisation kinetics undeniably should play a role in the local Ga depletion of the AlGaAs capping layer.

A number of structural details and the chemical analysis of GaAs/AlGaAs DE-QDs have been presented in this study. The QDs are found to be almost pure GaAs. GaAs intrusions were also found below a number of the QDs and attributed to local etching processes. This process was found to be responsible for major drilling and Al-intermixing for the largest QDs. An Al-rich capping of the high aspect ratio QDs was observed, which is attributed to the difference in mobility between cations. The fabrication of GaAs/AlGaAs QDs by DE is subject to phenomena altering the final dimensions and chemical composition of the QDs. GaAs DE-QDs have heights of several nm and diameters of several tens of nm,

hence, the quantum confinement is the strongest along the growth direction. The fluctuations of several nm in QD height arising from the etching mechanism undoubtedly compromise the final goal of controlling the optical emission of these DE-QDs. A high concentration of Al is known to favor the presence of structural defects in AlGaAs. The observed Al-rich crown is therefore expected to be detrimental to the optical emission. Preventing those phenomena is essential for keeping the control over the QD morphology that can be obtained by fine tuning growth parameters. From the presented investigations, the key factors are the kinetics of the crystallization which is dominated by the size of the Ga droplet and the resulting surface tensions. The formation of the Al-rich crown can thus be avoided by engineering the capping layer to flatten and control the height of the QDs.
