SHORT COMMUNICATION

The incorporation of gradient damage models in shell elements

Saman Hosseini¹, Joris J. C. Remmers¹ and René de Borst^{2,*}

SUMMARY

An approach is proposed to incorporate gradient-enhanced damage models in shell elements. The approach is elaborated for a solid-like shell element, which is advantageous because of the availability of nodes at the top and bottom shell surfaces, and the presence of a three-dimensional strain state. Some simple examples are given to demonstrate the versatility and the convergence of the method. Copyright © 2014 John Wiley & Sons, Ltd.

KEY WORDS: gradient damage models; solid-like shell; composite materials; intralaminar damage

1. INTRODUCTION

The failure behaviour of composite materials is often a combination of multiple damage mechanisms: delamination (interlaminar damage) and matrix cracking and fibre breakage (intralaminar damage). The complex nature of these failure mechanisms requires a reliable computational tool for the prediction of structural integrity.

Microcracks in the matrix are often the first form of damage in laminates. At a mesolevel, where the individual plies of a composite are modelled, matrix cracking can be represented through a continuum damage model [1]. After accumulation of a certain amount of damage, however, continuum damage models lead to ill-posed BVPs, which causes a severe mesh dependence [2]. Gradient damage models have been shown to be an efficient solution to this [3].

So far, gradient damage simulations have been restricted to continua, either two or three dimensional. Structural applications do not seem to have been reported. Bearing in mind that the stresses must be computed accurately for use in intralaminar damage models, solid-like shell elements such as that developed in References [4–6] seem to be particularly suitable. Because of the enhanced kinematics, a fully three-dimensional strain state exists within the shell, which enables the straightforward use of three-dimensional constitutive relations. The solid-like shell model has another advantage, namely that it carries only translational DOF. This not only makes it easy to stack them, but, because the translational DOFs are located at the top and bottom surfaces, the associated nodes can also be used for the interpolation of a nonlocal equivalent strain field. Indeed, because in a gradient damage model the nonlocal equivalent strain is interpolated in addition to the displacements, an assumption is required for this additional field as well.

†E-mail: Rene.DeBorst@glasgow.ac.uk

We propose to independently interpolate the nonlocal equivalent strain field at each surface of the shell. In the case of solid-like shell elements, the nodes that are needed for this interpolation are directly available. However, the same procedure can be used for other shell elements, by defining auxiliary nodes that are used for the interpolation of the nonlocal equivalent strain field only. These auxiliary nodes are then obtained from the mid-surface nodes, the local shell director and the thickness of the shell. With the nonlocal equivalent strain at the top and bottom surfaces at hand, its value anywhere inside the shell can be computed by a linear interpolation between the values at the top and the bottom surfaces, which assumption is consistent with the assumption that straight fibres remain straight.

For completeness, we first briefly summarize the gradient damage model and the solid-like shell element. We next show how the gradient damage model can be incorporated in a solid-like shell element. Some simple examples are given to demonstrate the versatility and mesh independence.

2. DAMAGE MODEL

In this paper, we assume an isotropic damage model which means that one damage variable, ω , describes the damage process. Herein, the undamaged material is characterized by $\omega = 0$ and the fully damaged material by $\omega = 1$ (in practice, a value close to 1 is used to avoid ill-conditioning of the local stiffness matrix). Assuming small strains, the following relation between the second Piola–Kirchhoff stress tensor $\mathbf{S}$ and the Green–Lagrange strain tensor $\boldsymbol{\gamma}$ is adopted:

$$\mathbf{S} = (1 - \omega)\mathbf{C} : \boldsymbol{\gamma} \quad (1)$$

with $\mathbf{C}$ as the elastic stiffness matrix. In this relation, the damage variable is given as

$$\omega = \omega(\kappa) \quad (2)$$

with κ as a history parameter, which retains the most severe deformation. The damage model is completed by a loading function f as a function of the nonlocal equivalent strain $\bar{\gamma}_{eq}$:

$$f(\gamma, \kappa) = \bar{\gamma}_{eq}(\gamma) - \kappa \quad (3)$$

The history parameter starts at a threshold value κ_i and is updated through the Kuhn–Tucker loading–unloading conditions:

$$f \leq 0 \quad , \quad \dot{\kappa} \geq 0 \quad , \quad f \dot{\kappa} = 0 \quad (4)$$

Following [3], the nonlocal equivalent strain $\bar{\gamma}_{eq}$ follows from the solution of the partial DE

$$\bar{\gamma}_{eq} - c \nabla^2 \bar{\gamma}_{eq} = \gamma_{eq} \quad (5)$$

where $\gamma_{eq} = \gamma_{eq}(\boldsymbol{\gamma})$ is the local equivalent strain and c sets the internal length scale.

3. VIRTUAL WORK AND LINEARIZATION

In a total Lagrangian formulation, the principle of virtual work is expressed in the reference configuration Ω_0

$$\int_{\Omega_0} \delta \boldsymbol{\gamma}^T : \mathbf{S} \, d\Omega_0 = \int_{\Gamma_0} \delta \mathbf{u}^T \mathbf{t}_0 \, d\Gamma_0 \quad (6)$$

with $\mathbf{t}_0$ the traction acting on the boundary Γ_0 of the initial configuration. Note that neither body forces nor follower forces have been taken into account. The resulting system of nonlinear equations is typically solved using the Newton–Raphson method, which requires computation of the tangential stiffness matrix. This quantity is obtained by linearizing the internal virtual work, the left side of Equation (6):

$$\mathcal{D}(\delta W_{int}) = \int_{\Omega_0} (\delta \boldsymbol{\gamma} : \mathcal{D}\mathbf{S} + \mathcal{D}(\delta \boldsymbol{\gamma}) : \mathbf{S}) \, d\Omega_0 \quad (7)$$

Using Equation (1), the derivative of the stress tensor is written as

$$\mathcal{D}\mathbf{S} = (1 - \omega)\mathbf{C} : \mathcal{D}\boldsymbol{\gamma} - \frac{\partial\omega}{\partial\kappa} \frac{\partial\kappa}{\partial\bar{\gamma}_{eq}} \mathcal{D}\bar{\gamma}_{eq} \mathbf{C} : \boldsymbol{\gamma} \quad (8)$$

where $\partial\kappa/\partial\bar{\gamma}_{eq} \equiv 1$ for loading and $\partial\kappa/\partial\bar{\gamma}_{eq} \equiv 0$ for unloading. Defining

$$q = \frac{\partial\omega}{\partial\kappa}$$

and substituting Equation (8) into Equation (7), the linearized internal virtual work expression becomes

$$\mathcal{D}(\delta W_{int}) = \int_{\Omega_0} (\delta\boldsymbol{\gamma} : (1 - \omega)\mathbf{C} : \mathcal{D}\boldsymbol{\gamma} - q\mathcal{D}\bar{\gamma}_{eq} \delta\boldsymbol{\gamma} : \mathbf{C} : \boldsymbol{\gamma}) d\Omega_0 + \int_{\Omega_0} \mathcal{D}(\delta\boldsymbol{\gamma}) : \mathbf{S} d\Omega_0 \quad (9)$$

where the last term leads to the standard geometric stiffness matrix, which will not be repeated here.

Equation (5) is coupled to the equilibrium Equation (6) and must be solved concurrently. The variational form of the gradient damage Equation (5) is given by

$$\int_{\Omega_0} \delta\bar{\gamma}_{eq} (\bar{\gamma}_{eq} - c\nabla^2\bar{\gamma}_{eq} - \gamma_{eq}) d\Omega_0 = 0 \quad (10)$$

In line with the vast majority of the literature, a natural boundary condition is assumed for $\bar{\gamma}_{eq}$. Application of the divergence theorem then leads to

$$\int_{\Omega_0} (\delta\bar{\gamma}_{eq} \bar{\gamma}_{eq} + c\nabla\delta\bar{\gamma}_{eq} \cdot \nabla\bar{\gamma}_{eq}) d\Omega_0 - \int_{\Omega_0} \delta\bar{\gamma}_{eq} \gamma_{eq} d\Omega_0 = 0 \quad (11)$$

For the derivation of the tangent stiffness matrix, this expression must be linearized, leading to

$$\int_{\Omega_0} (\delta\bar{\gamma}_{eq} \mathcal{D}\bar{\gamma}_{eq} + c\nabla\delta\bar{\gamma}_{eq} \cdot \nabla\mathcal{D}\bar{\gamma}_{eq}) d\Omega_0 - \int_{\Omega_0} \delta\bar{\gamma}_{eq} \mathcal{D}\gamma_{eq} d\Omega_0 = 0 \quad (12)$$

where

$$\mathcal{D}\gamma_{eq} = \mathbf{p}^T \mathcal{D}\boldsymbol{\gamma} \quad , \quad \mathbf{p}^T = \frac{\partial\gamma_{eq}}{\partial\boldsymbol{\gamma}} \quad (13)$$

4. SOLID-LIKE SHELL FORMULATION

Figure 1 shows the reference and the current configuration, and the kinematics of the solid-like shell element in curvilinear coordinates. The element kinematics are captured by a linear combination of a pair of material points at the top and at the bottom surfaces of the element. Each point is characterized by a position vector, $\mathbf{X}_t$ and $\mathbf{X}_b$ for the initial configuration on the top and bottom surfaces, respectively. The variables ξ and η are the local curvilinear coordinates in the two independent in-plane directions, and ζ is the local curvilinear coordinate in the thickness direction.

Figure 1. Geometry and kinematics of the shell in the undeformed and deformed configurations.

The position of a material point in the undeformed configuration is written as function of three curvilinear coordinates

$$\mathbf{X}(\xi, \eta, \zeta) = \mathbf{X}^0(\xi, \eta) + \zeta \mathbf{D}(\xi, \eta) \quad (14)$$

where $\mathbf{X}^0(\xi, \eta)$ is the projection of the point on the mid-surface of shell and $\mathbf{D}$ is the thickness director in this point:

$$\mathbf{X}^0(\xi, \eta) = \frac{1}{2} [\mathbf{X}_t(\xi, \eta) + \mathbf{X}_b(\xi, \eta)] \quad , \quad \mathbf{D}(\xi, \eta) = \frac{1}{2} [\mathbf{X}_t(\xi, \eta) - \mathbf{X}_b(\xi, \eta)] \quad (15)$$

The position of the material point in the deformed configuration $\mathbf{x}(\xi, \eta)$ is related to $\mathbf{X}(\xi, \eta)$ via the displacement field $\mathbf{u}(\xi, \eta, \zeta)$ as

$$\mathbf{x}(\xi, \eta, \zeta) = \mathbf{X}(\xi, \eta, \zeta) + \mathbf{u}(\xi, \eta, \zeta) \quad (16)$$

where

$$\mathbf{u}(\xi, \eta, \zeta) = \mathbf{u}^0(\xi, \eta) + \zeta \mathbf{u}^1(\xi, \eta) + (1 - \zeta^2) \mathbf{u}^2(\xi, \eta) \quad (17)$$

In this relation, $\mathbf{u}^0$ and $\mathbf{u}^1$ are the displacements of $\mathbf{X}^0$ on the shell mid-surface and the thickness director $\mathbf{D}$, and can be written as

$$\mathbf{u}^0(\xi, \eta) = \frac{1}{2} [\mathbf{u}_t(\xi, \eta) + \mathbf{u}_b(\xi, \eta)] \quad , \quad \mathbf{u}^1(\xi, \eta) = \frac{1}{2} [\mathbf{u}_t(\xi, \eta) - \mathbf{u}_b(\xi, \eta)] \quad (18)$$

The internal stretch of the element is represented in Equation (17) by the inclusion of a quadratic term in the displacement field, so that the normal strain in the thickness direction varies linearly. $\mathbf{u}^2$ is expressed in terms of stretch DOFs, w , as

$$\mathbf{u}^2 = w(\xi, \eta) [\mathbf{D}(\xi, \eta) + \mathbf{u}^1(\xi, \eta)] \quad (19)$$

see also Figure 1.

In any material point, a local reference triad can be established. The covariant base vectors are then obtained as the partial derivatives of the position vectors with respect to the curvilinear coordinates $\Theta = [\xi, \eta, \zeta]$. In the undeformed configuration, they are defined as

$$\mathbf{G}_\alpha = \frac{\partial \mathbf{X}}{\partial \Theta^\alpha} = \mathbf{E}_\alpha + \zeta \mathbf{D}_{,\alpha} \quad , \quad \alpha = 1, 2 \quad , \quad \mathbf{G}_3 = \mathbf{D} \quad (20)$$

where $(\cdot)_{,\alpha}$ denotes the partial derivative with respect to Θ^α . $\mathbf{E}_\alpha = \frac{\partial \mathbf{X}^0}{\partial \Theta^\alpha}$, is the covariant base vector defined on the mid-surface. Similarly, in the deformed configuration, we have

$$\begin{aligned} \mathbf{g}_\alpha &= \frac{\partial \mathbf{x}}{\partial \Theta^\alpha} = \mathbf{G}_\alpha + \mathbf{u}^0_{,\alpha} + \zeta \mathbf{u}^1_{,\alpha} + (1 - \zeta^2) \mathbf{u}^2_{,\alpha} \\ \mathbf{g}_3 &= \mathbf{D} + \mathbf{u}^1 - 2\zeta \mathbf{u}^2 \end{aligned} \quad (21)$$

Using Equations (20) and (21), the components G_{ij} and g_{ij} of the metric tensors in the undeformed and the deformed configuration, respectively, can be determined as

$$G_{ij} = \mathbf{G}_i \cdot \mathbf{G}_j \quad , \quad g_{ij} = \mathbf{g}_i \cdot \mathbf{g}_j \quad , \quad i = 1, 2, 3 \quad (22)$$

and finally, the representation of the Green-Lagrange strain tensor reads as

$$\boldsymbol{\gamma} = \gamma_{ij} \mathbf{G}^i \otimes \mathbf{G}^j \quad \text{with} \quad \gamma_{ij} = \frac{1}{2} (g_{ij} - G_{ij}) \quad (23)$$

From Equations (21)–(23), we infer that

$$\boldsymbol{\gamma} = \boldsymbol{\gamma}(\mathbf{u}^0, \mathbf{u}^1, \mathbf{u}^2) \quad (24)$$

and using Equations (18) and (19),

$$\boldsymbol{\gamma} = \boldsymbol{\gamma}(\mathbf{u}_b, \mathbf{u}_t, w) = \boldsymbol{\gamma}(\mathbf{u}, w) \quad (25)$$

with $\mathbf{u} = (\mathbf{u}_b, \mathbf{u}_t)$ collecting the displacement DOFs at the bottom and top surfaces. For future, use we list the variation of the strain tensor:

$$\delta \boldsymbol{\gamma} = \frac{\partial \boldsymbol{\gamma}}{\partial \mathbf{u}} \delta \mathbf{u} + \frac{\partial \boldsymbol{\gamma}}{\partial w} \delta w \quad (26)$$

5. FINITE ELEMENT IMPLEMENTATION

In this paper, we consider the sixteen-node solid-like shell element (Figure 2). Each node contains three displacement DOFs, a_x, a_y, a_z , which gives a bi-quadratic interpolation of the in-plane displacement field. With this interpolation for the displacements, the nonlocal equivalent strain field $\bar{\gamma}_{eq}$ should be interpolated using bi-linear shape functions to avoid oscillations [7]. Hence, the corner nodes of the solid-like shell element have DOFs for the nonlocal equivalent strain field. It is recalled that the nodes of the top surface are used for the interpolation of the nonlocal equivalent strain field at the top surface, and those of the bottom surface support the nodal parameters of the nonlocal equivalent strain field at the bottom surface. The nonlocal equivalent strain at any point in the shell is then found by an interpolation in the thickness direction of the values of the nonlocal equivalent strain at the top and bottom surfaces. The kinematics of the shell are completed by a linear distribution of the internal stretch, which is supported by DOFs located at the four corners of the mid-surface of the element. As detailed in References [4–6], these are internal DOFs and are condensed at element level.

We discretize the displacement, the stretch and the nonlocal equivalent strain as

$$\mathbf{u} = \mathbf{H}_u \mathbf{a}, \quad w = \mathbf{H}_w \mathbf{w}, \quad \bar{\gamma}_{eq} = \mathbf{H}_{\bar{\gamma}} \mathbf{e} \quad (27)$$

where $\mathbf{H}_u, \mathbf{H}_w, \mathbf{H}_{\bar{\gamma}}$ contain the corresponding shape functions and $\mathbf{a}, \mathbf{w}, \mathbf{e}$ are the vectors containing the DOFs for the displacement, the stretch and the nonlocal equivalent strain, respectively. The strain and the gradient of the nonlocal equivalent strain then become

$$\boldsymbol{\gamma} = \mathbf{B}_u \mathbf{a} + \mathbf{B}_w \mathbf{w}, \quad \nabla \bar{\gamma}_{eq} = \mathbf{B}_{\bar{\gamma}} \mathbf{e} \quad (28)$$

with $\mathbf{B}_u, \mathbf{B}_w, \mathbf{B}_{\bar{\gamma}}$ as the matrices that contain the derivatives of the shape functions.

Substituting (27) and (28) for the variational forms in (6) and (11) and requiring that the results hold for arbitrary $(\delta \mathbf{a}, \delta \mathbf{w}, \delta \mathbf{e})$, the discrete equilibrium equations are obtained as

$$\int_{\Omega_0} \mathbf{B}_u^T \mathbf{S} \, d\Omega_0 = \int_{\Gamma_0} \mathbf{H}_u^T \mathbf{t}_0 \, d\Gamma_0 \quad (29)$$

$$\int_{\Omega_0} \mathbf{B}_w^T \mathbf{S} \, d\Omega_0 = \mathbf{0} \quad (30)$$

and averaging equation for the nonlocal equivalent strains becomes

$$\int_{\Omega_0} (\mathbf{H}_{\bar{\gamma}}^T \mathbf{H}_{\bar{\gamma}} + c \mathbf{B}_{\bar{\gamma}}^T \mathbf{B}_{\bar{\gamma}}) \, d\Omega_0 - \int_{\Omega_0} \mathbf{H}_{\bar{\gamma}_{eq}}^T \gamma_{eq} \, d\Omega_0 = 0 \quad (31)$$

Figure 2. Geometry of 16 noded solid-like shell element.

The left-hand sides of Equations (29)–(31) lead to the internal force vectors, which can be differentiated to yield the material part of the tangential stiffness matrix:

$$\mathbf{K} = \begin{bmatrix} \mathbf{K}_{aa} & \mathbf{K}_{aw} & \mathbf{K}_{ae} \\ \mathbf{K}_{wa} & \mathbf{K}_{ww} & \mathbf{K}_{we} \\ \mathbf{K}_{ea} & \mathbf{K}_{ew} & \mathbf{K}_{ee} \end{bmatrix} \quad (32)$$

where

$$\begin{aligned} \mathbf{K}_{aa} &= \int_{\Omega_0} (1 - \omega) \mathbf{B}_u^T \mathbf{C} \mathbf{B}_u \, d\Omega_0 & \mathbf{K}_{aw} &= \int_{\Omega_0} (1 - \omega) \mathbf{B}_u^T \mathbf{C} \mathbf{B}_w \, d\Omega_0 \\ \mathbf{K}_{ae} &= \int_{\Omega_0} q \mathbf{B}_u^T \mathbf{C} \gamma_{eq} \mathbf{H}_{\bar{\gamma}} \, d\Omega_0 & \mathbf{K}_{wa} &= \int_{\Omega_0} (1 - \omega) \mathbf{B}_w^T \mathbf{C} \mathbf{B}_u \, d\Omega_0 \\ \mathbf{K}_{ww} &= \int_{\Omega_0} (1 - \omega) \mathbf{B}_w^T \mathbf{C} \mathbf{B}_w \, d\Omega_0 & \mathbf{K}_{we} &= \int_{\Omega_0} q \mathbf{B}_w^T \mathbf{C} \gamma_{eq} \mathbf{H}_{\bar{\gamma}} \, d\Omega_0 \\ \mathbf{K}_{ea} &= - \int_{\Omega_0} \mathbf{H}_{\bar{\gamma}}^T \mathbf{p}^T \mathbf{B}_u \, d\Omega_0 & \mathbf{K}_{ew} &= - \int_{\Omega_0} \mathbf{H}_{\bar{\gamma}}^T \mathbf{p}^T \mathbf{B}_w \, d\Omega_0 \\ \mathbf{K}_{ee} &= \int_{\Omega_0} \left(\mathbf{H}_{\bar{\gamma}eq}^T \mathbf{H}_{\bar{\gamma}eq} + c \mathbf{B}_{\bar{\gamma}eq}^T \mathbf{B}_{\bar{\gamma}eq} \right) \, d\Omega_0 \end{aligned} \quad (33)$$

A 2×2 Gauss integration rule has been adopted for the in-plane integration for all submatrices, and Newton–Cotes integration has been used through the thickness. In the example, a five-point Newton–Cotes integration was sufficient.

6. EXAMPLES

We will now assess the implementation of the enhanced gradient damage model by means of two examples.

6.1. Simulation of continuum damage

A 3 mm-thick bar of length $L = 100$ mm and of 3.3 mm width (Figure 3) is considered which is subjected to a uniaxial tensile load. To trigger localization, the cross-sectional area in the centre part of the bar has been reduced by 10% over a length $l = 10$ mm. A Young's modulus $E = 2000$ N/mm², a fracture energy $G_c = 0.001$ N/mm and a tensile strength $f_t = 2$ N/mm² have been used, together with a linear damage evolution law and $c = 1$ mm² [3]. The load-displacement graph is shown in Figure 4 for various levels of mesh refinement. As in previous simulations [3], a proper convergence upon mesh refinement is observed.

6.2. Panel under distributed load

The previous example assesses the convergence for in-plane loadings, but not for a plate that is subject to bending. This is subject of the next example, which is shown in Figure 5. The panel has a length $l = 500$ mm, a width $b = 250$ mm, a thickness $t = 10$ mm, and is clamped on both ends. A Young's modulus $E = 4000$ N/mm², a fracture energy $G_c = 0.05$ N/mm and a tensile strength $f_t = 2$ N/mm² have been chosen with a linear damage relation and $c = 1$ mm². As in the previous example, the simulations have been repeated for different mesh sizes. The results are shown in Figure 6, which show a clear mesh independence. Figure 7 also shows the deformation of the panel and the intensity of the damage evolution.

Figure 3. Bar with an imperfection subjected to an axial tension.

Figure 4. Load-displacement graph of the bar under tension.

Figure 5. Geometry of the panel under sinusoidal traction.

Figure 6. Load-displacement graph of the panel under sinusoidal traction.

Figure 7. Deformation and damage intensity of the panel.

7. CONCLUDING REMARKS

An approach to incorporate gradient damage models in shell elements has been proposed. The implementation was performed in a solid-like shell element, which has advantages because a three-dimensional stress state is available, and because of the presence of nodes at the top and bottom surfaces. The latter enables the direct interpolation of the nonlocal equivalent strain at the shell surfaces, from which the nonlocal equivalent strain in the interior of the shell is obtained by a linear interpolation. Examples show the versatility of the approach and the convergence upon mesh refinement.
