Microwave Photonic Integrated Circuits for Millimeter-Wave Wireless Communications

Abstract—This paper describes the advantages that the introduction of photonic integration technologies can bring to the development of photonic-enabled wireless communications systems operating in the millimeter wave frequency range. We present two approaches for the development of dual wavelength sources for heterodyne-based millimeter wave generation realized using active/passive photonic integration technology. One approach integrates monolithically two distributed feedback semiconductor lasers with semiconductor optical amplifiers, wavelength combiners, electro-optic modulators and broad bandwidth photodiodes. The other uses a generic photonic integration platform, developing narrow linewidth dual wavelength lasers based on arrayed waveguide gratings. Moreover, data transmission over a wireless link at a carrier wave frequency above 100 GHz is presented, in which the two lasers are free-running, and the modulation is directly applied to the single photonic chip without the requirement of any additional component.

Index Terms—Broadband communication, microwave photonics, millimeter wave communication, millimeter wave integrated circuits, photonic integrated circuits, semiconductor lasers.

I. INTRODUCTION

PHOTONIC techniques have become key enablers to unlock future broadband wireless communications with multi-gigabit data rates in order to support the current trends of mobile data traffic, which is expected to increase 13-fold between 2012 and 2017 [1]. It is estimated that complex modulation formats making more efficient use of the spectrum will not suffice, and moving to carrier frequencies into the millimeter wave frequency range (30 to 300 GHz) will be necessary.

as the wavelength separation has to be larger than the combined widths of the stop bands of the two lasers so each one is transparent to the other.

Pushing the boundaries in millimeter wave wireless applications was the objective of the European Commission funded project iPHeS (Integrated photonic transceivers at sub-terahertz wave range for ultra-wideband wireless communications). This project established a crossroad between photonic-enabled millimeter-wave technologies and photonic integration efforts to support advanced wireless communications in the E-band (60–90 GHz) and F-band (90–140 GHz) [10], having already demonstrated a wireless link using two free-running monolithically integrated DFB lasers to generate a 146 GHz carrier, transmitting non-return-to-zero OOK at a data rate of 1 Gbps using external modulation [11].

This paper presents the two approaches that were pursued within the iPHeS project to develop a photonic integrated circuit (PIC) dual wavelength source for heterodyne-based millimeter wave generation. The two device structures are described in Section II. The characterization and performance of both devices, realized using two distinct active/passive integration technologies, is presented in Section III. Finally, Section IV describes a wireless link data transmission at a carrier wave frequency above 100 GHz, in which the two sources are free-running. As an advantage, a narrow channel bandwidth limitation of the structure, as the wavelength spacing is not continuously tunable.

A. Dual Distributed Feedback Approach

The developed monolithic millimeter-wave wireless transmitter on a chip is presented in Fig. 1. As shown, it includes two DFB lasers of 1 mm length, both having a phase shift written on a chip to avoid this limitation.

Fig. 1. Microscope view of the dual DFB dual wavelength source.
defined by e-beam lithography. The UTC layers are similar to the ones used in [15], are grown above the passive waveguide, to implement two $3 \times 15\, \mu\text{m}$ UTC-PD. The fabrication required 3 epitaxial growth steps. After wafer thinning and back metal deposition a first set of measurements were performed directly on the wafer. After these first measurements, chips were cleaved and mounted on AlN submounts.

B. Arrayed Waveguide Grating Approach

The alternative multi-wavelength structure that we present is based on an AWG laser using novel multimode interference reflectors (MIR) to define the mirrors [16], achieving a new fully monolithic structure. It is fabricated using active/passive integration on an InP technology multi-project wafer run, following the schematic in Fig. 2. The device has an extended cavity configuration built around the AWG, which acts as an intra-cavity filter. Since the cavity loss is minimal for a specific wavelength within each channel passband of the AWG, activating each channel SOA by current injection generates a specific wavelength. The common arm of the AWG multiplexes all the channel wavelengths on the common waveguide.

The novelty of the proposed device is that the AWG channel and common waveguides are terminated in MIR mirrors, using either a $2 \times 0$ mirror configuration when an optical output is desired (as shown for Channel type A in Fig. 2) or a $1 \times 0$ configuration to produce total reflection of the optical power (as shown for Channel type B). All AWG channels must include one SOA, to activate the corresponding channel wavelength. The two types of channels that we have defined in Fig. 2 differentiate whether it includes an Electro-Optic Phase Shifter (PHS) to allow wavelength tuning (channel type B) or it does not (channel type A). An output SOA, located at the common output of the chip, allows the optical output power from the chip to be boosted. The common waveguide routes the output power to an angled waveguide at an AR-coated facet to minimize back reflections.

Fig. 3 presents one realization of this photonic integrated circuit, produced within an InP technology multi-project wafer run. It shows a four channel AWG, with 1000-\textmu m long SOAs at each channel. The AWG central wavelength is $\lambda_0 = 1550\, \text{nm}$, the channel spacing $\Delta\lambda = 120\, \text{GHz}$ (0.96 nm) and the free spectral range (FSR) is 700 GHz ($\sim 6\, \text{nm}$). The two upper channels are type A, and the two bottom ones, type B, with 1000-\textmu m long PHS each. All the channels are terminated with $1 \times 0$ MIR, to reduce the optical losses at the channels. The common arm of the AWG uses a $2 \times 0$ MIR to provide the multi-wavelength output, with 750-\textmu m long output SOA. The total cavity length for type A channels is approximately 3.25 mm, 5 mm shorter than the AWG device presented in Ref. [16].

III. DEVICE CHARACTERIZATION

A. Dual Distributed Feedback Devices

Using the left-hand side optical output of the device shown in Fig. 1, we have been able to measure simultaneously the spectrum of the optical signal generated by the chip and the generated high frequency electrical signal from the monolithically integrated UTC photodiodes when the DFB lasers were electrically tuned and some of the SOAs biased.

For the measurements showing the tuning range of the two wavelengths, one of the DFB lasers was biased with a current varying from 50 to 86 mA while the other was biased with a current varying within a 50 to 198 mA range. Within these bias ranges, the UTC photocurrent varied between 1.12 and 6.27 mA. During operation, the photodiode is reversed biased at 2.5 V. Dark current of $<10\, \text{uA}$ was measured at this bias point.

The measured optical spectra are presented in Fig. 4, where for the shown sample a continuous tuning of the optical frequency difference between the two DFB tones from 5 to
110 GHz is observed. The wavelength tuning is thermal through changes in the DFB bias current. Also, as the two lasers are close to each other, we observe thermal cross-talk between the two lasers. For the upper curves on the graph (5–50 GHz), there is an additional optical tone. This is due to the tendency of each DFB lasers to have a dual mode behavior for higher bias currents. Indeed the DFB lasers, with an integrated phase shift, are single mode in the ideal case, where there are no reflections. In the integrated chip there are some residual reflections that can occur, for example, on the butt joints, in the MMI coupler or on the back of the photodiodes.

The linewidth of each laser was evaluated separately using the delayed self-heterodyne technique [17], with the result being presented in Fig. 5. Using a Lorentzian fit, the FWHM linewidth was assessed to be about 2 MHz for the DFB lasers with single-electrode and about 3 MHz for the DFB lasers which includes an additional, 100 um long passive PS for laser wavelength tuning.

The electrical spectra, shown in Fig. 6, were measured using a Rohde & Schwarz FSU67 electrical spectrum analyzer, with a FS-Z110 external mixer for measurements above 65 GHz.

Presence of the additional optical tone does not prevent the generation of the lower frequency range beat notes. Nevertheless, these additional optical mode lines may have a negative effect generating a photocurrent that is not useful for the purpose of signal generation and can potentially limit the maximum mm-wave power delivered. However, within the intended millimeter wave frequency ranges allocated to wireless in the E-band (71–76 and 81–86 GHz) the device is a dual mode source.

We were able to observe the beat note on the photodiode port over the full tuning range. In order to have a better idea of the bandwidth of the integrated photodiodes, we have corrected the power level of the detected high frequency tones by subtracting the losses of the cables and the probes and by normalizing it based on the measured photocurrent, estimating that the bandwidth of the photodiode is above 85 GHz. Further measurements on discrete devices cleaved from the wafers are needed in order to assess the bandwidth of these monolithic photodiodes.

The following test was done in order to determine the maximum electrical output power that could be generated at the integrated photodiode. The power emitted from the WR08 horn antenna at the RF probe was detected using an Agilent E4418B EPM series power meter with a W8486A power sensor with frequency range from 75 to 110 GHz. The two DFB lasers were biased at 95 mA, giving the generated beat note frequency 95.7 GHz. As shown on Fig. 7, by changing the current of the optical amplifiers at the output of each DFB (SOA1.1 and SOA2.1, which are connected to the same electrical contact on the submount), we demonstrate a maximum detected power of $-12$ dBm when the photodiode is reversed biased to $-2.5$ V with 8.76 mA generated photocurrent. The losses due to RF probe and signal free space propagation path (<3 cm) between antenna on the probe and power meter are not corrected.

### B. Arrayed Waveguide Grating Devices

The AWG laser behavior can be assessed from both the channel and the common optical outputs. For this device, we have first measured the $L-I$ characteristic at one of the outputs of a type B channel, with the phase shifter in open circuit. The optical spectrum is measured simultaneously on a Yokogawa.
Fig. 8. $L-I$ characteristic curve at the channel output on a Type B channel. As the channel SOA is biased, the phase shifter remains in open circuit.

Fig. 9. Optical spectrum evolution at the channel output on a Type B channel under the same conditions as Fig. 7.

The $L-I$ trace as the channel SOA current increases is shown in Fig. 8 and the evolution of the corresponding optical spectrum on Fig. 9. For the $L-I$ trace at the channel output, the EOPMs of both channels are kept disabled. The output optical power at 120 mA is about 250 $\mu$W and the threshold current value ($I_{th}$) is about 44 mA. From the two figures, we conclude that the device emits in a single optical mode, and the kinks in the $L-I$ trace correspond with jumps of the mode between adjacent FSR orders of the AWG. We have observed that the PHS can be used to control the FSR order in which the optical mode emits, rather than controlling a wavelength tuning mechanism, as the emission wavelength is strongly defined by the AWG channel.

When the $L-I$ characteristic is measured at the common output, we have to specify the current level for the Output SOA. The measured optical power for a channel SOA bias of 120 mA is about 250 $\mu$W and the threshold current value ($I_{th}$) is about 44 mA. From the two figures, we conclude that the device emits in a single optical mode, and the kinks in the $L-I$ trace correspond with jumps of the mode between adjacent FSR orders of the AWG. We have observed that the PHS can be used to control the FSR order in which the optical mode emits, rather than controlling a wavelength tuning mechanism, as the emission wavelength is strongly defined by the AWG channel.

AQ6370B Optical Spectrum Analyzer, splitting the optical signal to the optical power meter with a 90/10 splitter (90% to the power meter and 10% to the OSA).

Reference [16], we have seen that the dual wavelength behavior regions are reduced due to mode competition of the two modes in this SOA.

To establish the dual-wavelength regions of the AWG laser with MMI reflectors, we have measured the optical output from the common output, when the channel SOA of two adjacent channels are biased. One channel is kept at a fixed current level above threshold (80 mA) while the other is swept from 44 mA (threshold level) to 100 mA in steps of 2 mA. The output SOA is also fixed at a constant bias level of 10 mA. As shown in Fig. 10, the device has a dual mode behavior over the entire current range. Above 70 mA, we find that lasing starts at a higher order of the AWG FSR. However as the frequency difference with this new FSR order is above 700 GHz, it would be suppressed by the photodiode bandwidth. A delayed self-heterodyne measurement with Lorentzian fit to extract linewidth, shown in Fig. 11 reveals an optical linewidth below 100 kHz. The beat note spectrum measured using a fast photodiode (XPDV4120R) and FS-110...

external mixer is shown at the inset with the two central adjacent channel SOAs biased at 80 mA and 50 mA respectively, and the output SOA at 60 mA to increase the optical output power.

Although the emission wavelengths are fixed by the channel pass-bands of the AWG, this structure has been shown to produce optical modes with very narrow optical linewidth (<200 kHz) without any phase noise reduction scheme, separated at multiples of the channel spacing which enables them to generate signals within the THz region [18].

C. Comparison

We have shown that a dual wavelength source implemented by monolithic integration of two DFB has the great advantage of having a large tuning range, here demonstrated to cover the entire E-band range (60–90 GHz). The main concern is the linewidth of the optical modes. This is precisely the strong point for dual wavelength sources based on AWG lasers, exhibiting free running modes below 200 kHz. Due to the flexibility of the wavelength tuning, we have chosen the dual DFB devices to build a wireless data transmission experiment. In addition, this decision was based on the fact that the used device included a short SOA section at the angled facet to allow high-speed on-chip data modulation. It is worth highlighting that any on-chip modulator scheme (short SOA, EAM, Mach-Zehnder) that is external to the laser resonator can now be implemented to any of the presented designs, as both are fully monolithic structures that do not require the chip facets to establish the laser.

IV. WIRELESS LINK

The millimeter wave wireless data transmission experimental setup is shown in Fig. 12. The sample, shown in Fig. 13, was processed in the same batch as the sample presented in section II. It includes two 1 mm-long DFB lasers, one of which has an integrated passive phase shift section in the middle of the Bragg grating for wavelength tuning. The outputs of the two lasers are combined, after passing through SOAs, on a 2 × 1 MMI coupler, and then pass through an SOA (used as a modulator) before the waveguide outputs the light at the chip facet with an angled termination to minimize reflections.

The device is operated by biasing DFB1 at 95 mA, DFB2 at 240 mA, SOA1 at 51 mA, SOA2 at 40 mA and Mod at 60 mA. This produces two wavelengths at the output, as shown in Fig. 14, separated by 0.85 nm (which corresponds to an RF frequency of 105.4 GHz). The power difference between the two modes is around 0.7 dB and the power in the side modes at 1547 nm is 20 dB less than that of the DFB1 mode at 1548.65 nm. This optical signal is detected by a high speed photodiode (100 GHz bandwidth), and the resulting electrical signal is downmixed to 2.8 GHz with a Virginia Diodes Inc. Sub-harmonic mixer VDI WR08 mixer using a 51.3 GHz LO. The RF signal at the output of the photodiode has an electrical power of –11 dBm (1.25 mA into a 50 Ω load), and a 3 dB spectral width of about 10 MHz.

Data modulation at 1 Gbps is applied to the output SOA (Mod) of the integrated dual wavelength signal source. The optical output is coupled into a lensed fiber followed by three isolators to minimize the fiber reflection, coupling up to 6 dBm of optical power. This optical output is connected to our high speed photodiode (which has a DC responsivity of 0.48 A/W, with a 6 dB reduction at 120 GHz). The output of the photodiode is connected to a 23 dB F-band (90–140 GHz) horn antenna.

On the receiver end, a 20 dBi horn antenna is connected to the VDI sub-harmonic mixer to down-convert the RF to an IF signal, which is detected with a 3.5 GHz real time scope through a 20 dB gain RF amplifier. The real time scope is set to 10 Gs/s sampling rate, and sequences of 0.1 ms duration are recorded, corresponding to 10^9 bits for 1 Gbps modulation, to allow us to perform BER computation through post-processing.
Fig. 15. Eye diagram for 1 Gbps modulation with a modulation current of 7 mA. The PD DC current is 1.7 mA. No error is detected.

by performing a filtered envelope detector function. It is clear from the eye diagram shown in Fig. 15 that a modulation rate of 1 Gbps supports an open, error free signal. Higher data rates were tested, but the performance deteriorated significantly at 2 Gbps. We have found that back reflections at the facets cause a long cavity to form, using the boost SOA as gain section. This limits modulation bandwidth, and indicates that tilting the output waveguides 7° with respect to the chip facets is not sufficient to suppress back reflections, making AR coatings a requirement.

V. CONCLUSION

We have presented two different photonic integrated circuit approaches to generate carrier waves within the millimeter-wave frequency range. The approach using two monolithically integrated DFB lasers has the main advantage of the frequency tuning range, covering from 5 to 110 GHz in a single device. In addition, a process flow allowing fabrication on the same chip of lasers, optical amplifiers, modulators, and wide-bandwidth UTC photodiodes has been demonstrated. Electrical output powers up to −12 dBm at 95.7 GHz have been achieved. Using a dual DFB source from this fabrication batch, we have achieved wireless data transmission in which the data modulation signal has been directly introduced onto the chip. We have thus demonstrated the potential to integrate a photonic millimeter wave transmitter on a single chip, with an electrical data and bias inputs and an electrical output.

We also report for the first time a new class of dual wavelength sources, based on AWG lasers, which can be integrated within a chip thanks to the use on monolithic MIR reflectors. Although the emission wavelengths are fixed by the channel pass-bands of the AWG, this structure shows very narrow optical mode linewidths (below 200 kHz) without using any phase noise reduction scheme. In addition, thanks to the possibility of adding as many channels as needed in the design stage, it is straightforward to use these devices to generate signals within the THz region.
