A Coding Scheme for Additive Noise Channels with Feedback

Part II: Band-Limited Signals

J. PIETER M. SCHALKWIJK, MEMBER, IEEE

Abstract—In Part I of this paper, we presented a scheme for effectively exploiting a noiseless feedback link associated with an additive white Gaussian noise channel with no signal bandwidth constraints. We now extend the scheme for this channel, which we shall call the wideband (WB) scheme, to a band-limited (BL) channel with signal bandwidth restricted to $(-W, W)$. Our feedback scheme achieves the well-known channel capacity, $C = W \ln(1 + P_{av}/N_0W)$, for this system and, in fact, is apparently the first deterministic procedure for doing this. We evaluate the fairly simple exact error probability for our scheme and find that it provides considerable improvements over the best-known results (which are lower bounds on the performance of sphere-packed codes) for the one-way channel. We also study the degradation in performance of our scheme when there is noise in the feedback link.

I. INTRODUCTION

IN THIS PAPER a band-limited (BL) channel with feedback is considered. The signal bandwidth is restricted to $(-W, W)$.

A general introduction has been given in Part I, with particular attention to wideband (WB) channels.

The BL coding scheme developed here, is as far as we know, the first deterministic coding procedure to achieve the well-known capacity

$$C = W \ln[1 + (P_{av}/N_0W)].$$

To our knowledge, the only other results pertaining to the band-limited (BL) channel have been published by Elias [3]. He divided the channel into K subchannels of bandwidth $w = W/K$. If noiseless feedback is available and if $K \rightarrow \infty$, information can be sent at a rate equal to $W \ln[1 + (P_{av}/N_0W)]$. However, since the signal bandwidth is w instead of W , the coding and decoding complexity for the feedback scheme becomes an arbitrarily small fraction of that required without feedback.

II. A FEEDBACK COMMUNICATION SYSTEM WITH A CONSTRAINT ON THE BANDWIDTH

Let T be the time in seconds necessary for the transmission of a particular message. For the WB coding scheme discussed in Part I, as for orthogonal codes in one-way transmission, the bandwidth $W(T)$ of the transmission is an exponential function of the coding delay T .

This work was supported by NASA NsG 377.

The author is with the Applied Research Laboratory, Sylvania Electronic Systems, a division of Sylvania Electric Products Inc., Waltham, Mass.

In order to make the probability of error vanish for a fixed relative rate smaller than one, a large bandwidth is required.

Suppose now that one is given a fixed bandwidth W , which the transmission is not supposed to exceed. With this additional transmitter constraint imposed, the channel capacity C is no longer P_{av}/N_0 as before, but it now given by $W \ln[1 + (P_{av}/N_0W)]$, nats/second. For small values of P_{av}/N_0W the latter capacity approaches P_{av}/N_0 as it should, for when $W \rightarrow \infty$, both channels are identical.

Shannon [1] derives the capacity formula, $W \ln[1 + (P_{av}/N_0W)]$, by a random coding argument, and up till now no deterministic way was known for constructing a code achieving the critical rate for a band-limited white Gaussian noise channel with or without feedback. In this part the first such code will be developed for the case where noiseless feedback is available.

As in Part I, an optimization for finite block-length is carried through, the results are compared with bounds on one-way transmission plotted by Slepian [4], and the deterioration of the present scheme due to feedback noise is considered.

A. The BL Coding Scheme

In the WB coding scheme discussed in Part I, the variance of the estimate X_{N+1} for the message point θ was inversely proportional to the number N of iterations. The critical rate was $R_{crit} = (\ln N)/2T$ nats/second, and in order to achieve a constant rate one had to choose $N = e^{2AT}$, that is, the number of transmissions had to increase exponentially with time.

Now suppose one has to meet a bandwidth constraint W in cycles per second. In this case the number of independent transmissions can only increase linearly with time. The highest number of independent transmissions per second is approximately equal to $2W$. Substituting $N = 2WT$ in the equation for the critical rate above gives $R_{crit} = (\ln 2WT)/2T$ nats/second. Hence, $R_{crit} \rightarrow 0$ with increasing T , and so the system discussed in Part I has to be modified in order to achieve a constant rate different from zero in the band-limited case.

Two useful observations can be made at this point. First, while the critical rate approaches zero when we take $2W$ iterations per second the asymptotic relation $R_{crit}(T) \approx P_{av}(T)/N_0$ is still valid. In other words, both the rate and the average power approach zero for

increasing T . The limit of their ratio, however, is equal to the constant N_0 . The second observation is that X_{N+1} can be looked at as the maximum likelihood estimate of θ having observed $Y_1(X_1)$ through $Y_n(X_n)$, and assuming Gaussian noise, as explained in Part I-Section II.

With these two observations in mind, we shall present a coding scheme for the band-limited white Gaussian noise channel.

Suppose that transmissions take place at integer values of time, the time unit being $1/(2W)$ second. Numbers are sent again by amplitude modulating some basic waveform of bandwidth W and unit energy. The disturbance is white Gaussian noise (with spectral density $N_0/2$), and reception takes place using a matched filter.

The coding scheme starts out the same as in Part I-Section II. At the transmitter:

1) divide the unit interval $[0, 1]$ into M disjoint message intervals of equal length; let θ be the midpoint of the message interval corresponding to the particular message to be transmitted, and

2) at instant one, transmit $\alpha(X_{11} - \theta)$, where $X_{11} = 0.5$ and α is some constant to be determined later.

At the receiver:

1) receive $Y_{11}(X_{11}) = \alpha(X_{11} - \theta) + Z_{11}$, where Z_{11} is as before a Gaussian random variable with mean zero and variance $\sigma^2 = N_0/2$, and

2) compute $X_{12} = X_{11} - \alpha^{-1}Y_{11}(X_{11})$, then set $X_{21} = X_{12}$ and send X_{21} back to the transmitter.

Up to this point everything is the same as for the coding scheme of Part I-Section II-B. In other words, $X_{21} - \theta = -(1/\alpha)Z_{11}$, where X_{21} is the maximum likelihood estimate of θ having observed $Y_{11}(X_{11})$.

Now, in order to prevent the expected power per transmission from decreasing, as it did in the WB coding scheme, we shall take the next transmission as $g\alpha(X_{21} - \theta)$ instead of $\alpha(X_{21} - \theta)$, where the constant g will be determined presently. The receiver obtains the noisy observation

$$Y_{21}(X_{21}) = g\alpha(X_{21} - \theta) + Z_{21}$$

and then computes

$$X_{22} = X_{21} - (g\alpha)^{-1}Y_{21}(X_{21}).$$

We now have two independent estimates of θ :

$$X_{21} = \theta - \frac{1}{\alpha}Z_{11} \quad \text{and} \quad X_{22} = \theta - \frac{1}{g\alpha}Z_{21}.$$

For the value X_{31} to be sent back to the transmitter, we shall take the maximum likelihood estimate of θ having observed $Y_{11}(X_{11})$ and $Y_{21}(X_{21})$, that is, we shall set

$$X_{31} = \frac{\left(\frac{1}{g\alpha}\right)^2 X_{21} + \left(\frac{1}{\alpha}\right)^2 X_{22}}{\left(\frac{1}{\alpha}\right)^2 + \left(\frac{1}{g\alpha}\right)^2} = \frac{X_{21} + g^2 X_{22}}{1 + g^2}.$$

What is the variance of our successive maximum likelihood estimates X_{11} , X_{21} , and X_{31} ? It is known that

$$X_{21} \sim N\left(\theta, \frac{\sigma^2}{\alpha^2}\right) \quad \text{and} \quad X_{31} \sim N\left(\theta, \frac{\sigma^2}{\alpha^2} \frac{1}{1 + g^2}\right).$$

If, however, $g = (\alpha^2 - 1)^{1/2}$ is chosen, then

$$X_{31} \sim N\left(\theta, \frac{\sigma^2}{(\alpha^2)^2}\right).$$

In general, X_{i1} , $i = 2, 3, \dots$, is sent back. The next transmission is

$$\alpha^{i-1}(\alpha^2 - 1)^{1/2}(X_{i1} - \theta) \quad (1)$$

but the receiver obtains

$$Y_{i1}(X_{i1}) = \alpha^{i-1}(\alpha^2 - 1)^{1/2}(X_{i1} - \theta) + Z_{i1}$$

and then computes

$$X_{i2} = X_{i1} - [\alpha^{i-1}(\alpha^2 - 1)^{1/2}]^{-1}Y_{i1}(X_{i1})$$

and

$$X_{i+1,1} = \frac{X_{i1} + (\alpha^2 - 1)X_{i2}}{\alpha^2}.$$

The maximum likelihood estimate $X_{i+1,1}$ is normally distributed with mean θ and variance $\sigma^2/[(\alpha^2)^i]$, that is,

$$X_{i+1,1} \sim N\left[\theta, \frac{\sigma^2}{(\alpha^2)^i}\right]. \quad (2)$$

From this point on, the analysis is very similar again to that of Part I. Suppose the transmitter sends one of M possible messages, that is, the interval $[0, 1]$ is divided into M disjoint equal-length message intervals. The message point θ is the midpoint of the message interval corresponding to the particular message being transmitted. The probability of the receiver deciding on the wrong message interval (i.e., the probability of X_{N+1} lying outside the correct interval) is

$$P_e = 2 \operatorname{erfc} \left(\frac{\frac{1}{2}M^{-1}}{\sigma/\alpha^N} \right).$$

Now pick $M = \alpha^{N(1-\epsilon)}$, that is, $R = (\ln M)/N = (1 - \epsilon) \ln \alpha$, nats/dimension (the time unit was $1/(2W)$ seconds). This gives for the probability of error

$$P_e = 2 \operatorname{erfc} \left(\frac{\alpha^{N\epsilon}}{2\sigma} \right) \quad (3)$$

and thus,

$$\lim_{N \rightarrow \infty} P_e(N, \epsilon) = \begin{cases} 0 & \text{for } \epsilon > 0 \\ 1 & \text{for } \epsilon < 0. \end{cases}$$

In other words, the critical rate is equal to $R_{\text{crit}} = \ln \alpha$, nats/dimension. Putting $\alpha = e^A$ gives $R_{\text{crit}} = A$.

Next let us derive an expression for the average power P_{av} .

$$P_{av} = \frac{1}{T} E \left\{ \alpha^2 (X_{11} - \theta)^2 + \sum_{i=2}^N [\alpha^{i-1} (\alpha^2 - 1)^{1/2}]^2 (X_{i,1} - \theta)^2 \right\}$$

$$= \frac{1}{T} \left\{ \alpha^2 E(X_{11} - \theta)^2 + \sum_{i=2}^N [\alpha^{i-1} (\alpha^2 - 1)^{1/2}]^2 \frac{\sigma^2}{(\alpha^2)^{i-1}} \right\}.$$

Substituting $T = N/(2W)$ seconds, $\sigma^2 = N_0/2$, $\alpha = e^A$, and $E(X_{11} - \theta)^2 = 1/12$ (assuming a uniform prior distribution for θ), one gets

$$P_{av} = \frac{W e^{2A}}{6N} + \frac{N-1}{N} N_0 W (e^{2A} - 1). \quad (4)$$

Hence, asymptotically,

$$R_{crit} = \begin{cases} A = \frac{1}{2} \ln \left(1 + \frac{P_{av}}{N_0 W} \right) & \text{nats/dimension, or} \\ 2WA = W \ln \left(1 + \frac{P_{av}}{N_0 W} \right) & \text{nats/second} \end{cases} \quad (5)$$

which is the channel capacity as computed by Shannon [1]. This result proves that the BL coding system presented here achieves capacity for the band-limited white Gaussian noise channel. It is the first deterministic coding procedure to do so.

B. Optimization for Finite Blocklength

As in Part I, let us now investigate how far one falls short of the ideal when only permitting a finite coding delay N (in time units of $1/(2W)$ second).

In Section I-A, the slope α_i at the i th transmission was taken as

$$\alpha_i = \alpha^{i-1+\delta_{i1}} (\alpha^2 - 1)^{1/2(1-\delta_{i1})}$$

where

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j. \end{cases}$$

In order to make an optimization possible, an additional factor a is introduced, hence,

$$\alpha_i = a \alpha^{i-1+\delta_{i1}} (\alpha^2 - 1)^{1/2(1-\delta_{i1})} \quad i = 1, 2, 3, \dots \quad (6)$$

The receiver now has

$$Y_{i1}(X_{i1}) = \alpha_i (X_{i1} - \theta) + Z_{i1}$$

and computes

$$X_{i2} = X_{i1} - \alpha_i^{-1} Y_{i1}(X_{i1}),$$

$$X_{21} = X_{12},$$

and

$$X_{i+1,1} = \frac{X_{i1} + (\alpha^2 - 1)X_{i2}}{\alpha^2} \quad \text{for } i = 2, 3, \dots$$

Effectively, the introduction of the factor a reduces N_0 by a factor a^2 .

By (3), minimizing the probability of error is equivalent to maximizing the expression

$$a^2 \frac{\alpha^{2N\epsilon}}{2N_0} \quad (7)$$

where ϵ can be obtained from

$$R = (1 - \epsilon) \ln \alpha \text{ nats/dimension} \quad (8)$$

and $\sigma^2 = N_0/2$ was substituted for the variance.

Substituting $\alpha = e^A$ in (4) and allowing for the additional factor a leads to the following expression for the average power:

$$P_{av} = a^2 \left[\frac{W \alpha^2}{6N} + \frac{N-1}{N} \frac{N_0}{a^2} W (\alpha^2 - 1) \right]$$

which can be modified as

$$\frac{P_{av}}{N_0 W} = a^2 \frac{\alpha^2}{6N N_0} + \frac{N-1}{N} (\alpha^2 - 1). \quad (9)$$

Now assuming C , R , W , N_0 , and N constant, let us maximize (7) with respect to a^2 . Note that C and W constant implies $P_{av}/N_0 W$ constant, for

$$C = W \ln \left(1 + \frac{P_{av}}{N_0 W} \right).$$

Having gone through these preliminaries, one is now ready to perform the optimization. Set the derivative of $a^2 (\alpha^{2N\epsilon}/2N_0)$ equal to zero,

$$\frac{d}{da^2} \left(a^2 \frac{\alpha^{2N\epsilon}}{2N_0} \right) = \frac{\alpha^{2N\epsilon}}{2N_0} + a^2 \frac{d}{da^2} \left(\frac{\alpha^{2N\epsilon}}{2N_0} \right) \frac{d\alpha^2}{da^2}$$

$$+ a^2 \frac{d}{d\epsilon} \left(\frac{\alpha^{2N\epsilon}}{2N_0} \right) \frac{d\epsilon}{da^2} \frac{d\alpha^2}{da^2} = 0. \quad (10)$$

From (8) it follows that

$$\epsilon = 1 - \frac{2R}{\ln \alpha^2} \quad \text{and} \quad \frac{d\epsilon}{da^2} = \frac{2R}{\alpha^2} \frac{1}{(\ln \alpha^2)^2}$$

and from (9) it follows that

$$\frac{d\alpha^2}{da^2} = - \frac{\alpha^2}{a^2 + 6N_0(N-1)}.$$

Making these substitutions in (10) and putting the result equal to zero finally gives, after some algebra, the following simple expression for the optimum value a_0^2 of a^2 :

$$a_0^2 = 6N_0. \quad (11)$$

For the probability of error, substituting $\sigma^2 = N_0/2$ and $a_0^2 = 6N_0$ in (3), one has

$$P_e = 2 \operatorname{erfc} [(3\alpha^{2N})^{1/2}].$$

Solving for α^2 from (9) and (11) gives

$$\alpha^2 = \frac{N-1}{N} + \frac{P_{av}}{N_0 W}.$$

By (8) one has

$$\frac{R}{2W} = \ln \alpha^{1-\epsilon} \quad \text{or} \quad \alpha^{1-\epsilon} = \exp\left(\frac{R}{2W}\right)$$

where R is now in nats/second. Hence,

$$\alpha^\epsilon = \frac{\alpha}{\exp\left(\frac{R}{2W}\right)} = \frac{\left(\frac{N-1}{N} + \frac{P_{av}}{N_0 W}\right)^{1/2}}{\exp\left(\frac{R}{2W}\right)}$$

and finally,

$$P_e = 2 \operatorname{erfc} \left\{ \sqrt{3} \left[\frac{\frac{N-1}{N} + \frac{P_{av}}{N_0 W}}{\exp\left(\frac{R}{W}\right)} \right]^{N/2} \right\}. \quad (12)$$

This final result will be compared in the next section with the bounds on one-way communication as obtained by Slepian [4].

C. Comparison with Slepian's Results

In 1963 Slepian [4] plotted lower bounds on communication in the one-way case based on a geometrical approach to the coding problem for band-limited white Gaussian noise channels used by Shannon [2]. That is, there is no one-way communication system whose performance is any better than that plotted by Slepian. Figures 1 through 6 compare Slepian's curves (dashed lines) with the results described by (12) (solid lines). Note that the solid curves are exact, that is, they are not a bound as Slepian's curves are. The graphs presented are described in the following.

1) Figure 1 shows the signal-to-noise ratio $S/N = 10 \log_{10} (P_{av}/N_0 W)$ in decibels vs. the rate R/W in dits/cycle, as given by Shannon's capacity equation, $\ln [1 + (P_{av}/N_0 W)]$.

2) Figures 2(a) to 2(c) indicate the additional signal-to-noise ratio, in decibels above the value indicated in Fig. 1, required for a finite coding delay N , as a function of the rate in dits per cycle. The probability of error for the three figures is, respectively, $P_e = 10^{-2}$, 10^{-4} , and 10^{-6} . It is seen that a large improvement is obtained by going from $N = 5$ to $N = 15$, especially in the feedback scheme. Increasing the coding delay further does not result in much improvement.

3) Figures 3(a), and 3(b) are plots of the additional signal-to-noise ratio in decibels above the ideal value indicated in Fig. 1 vs. the coding delay N , for different values of the probability of error P_e and for a rate of $R/W = 0.2$ dit per cycle. Figure 3(b) represents a plot for the bounds computed by Slepian. Note that the curves for the feedback scheme in Fig. 3(a) indicate a much lower relative (to the ideal, given in Fig. 1) signal-to-noise ratio, except for extremely small values of N .

4) Figures 4(a) and (b) are plots of the probability of error vs. the coding delay N , with the signal-to-noise

ratio in decibels above the ideal as the parameter. The rate is $R/W = 0.2$ dit per cycle. Note the difference in shape between the two sets of curves.

5) Figure 5 is a plot of the relative rate R/C vs. the rate R/W in dits per cycle for different values of the coding delay. The probability of error is $P_e = 10^{-4}$.

6) Figures 6(a) and (b) are plots of the relative rate R/C vs. the coding delay N for different values of the signal-to-noise ratio.

D. Influence of Feedback Noise on the BL Coding Scheme

In this section, only the configuration in which $Y'_n(X'_n)$ (the received "number") is sent back will be investigated. The results for the case where X_n (the receiver's estimate) is sent back are similar to those in Part I in that the rate drops off to zero quickly.

Using the same notation as in Part I, it follows easily that

$$X'_{N+1,1} = X'_{N+1,1} + \alpha^{-1} Z'_{11} + \frac{\alpha^2 - 1}{\alpha^2} \sum_{i=2}^N \alpha_i^{-1} Z'_{i1} \quad (13)$$

where $\sum_{i=2}^1 = 0$, and α_i is given by (6). Hence,

$$X'_{N+1,1} \sim N \left\{ \theta, \frac{1}{\alpha^2} \left[\frac{\sigma'^2 + \sigma''^2}{\alpha^{2N}} + \frac{\sigma'^2}{\alpha^2} + \sigma''^2 (\alpha^{2(N-1)} - 1) \right] \right\}.$$

The variance σ_t^2 of the estimate X'_{N+1} of θ , as computed by the receiver, is

$$\sigma_t^2 = \frac{1}{\alpha^2} \left[\frac{\sigma'^2 + \sigma''^2}{\alpha^{2N}} + \frac{\sigma''^2}{\alpha^2} + \sigma''^2 (\alpha^{2(N-1)} - 1) \right]. \quad (14)$$

For the probability of error one has, from (3),

$$P_e = 2 \operatorname{erfc} \left[\frac{\alpha^{N(1-\epsilon)}}{2\sigma_t} \right] \quad (15)$$

where again $R = (1 - \epsilon) \ln \alpha$, nats/dimension.

The expression for the signal-to-noise ratio in the forward direction is, from (9),

$$\frac{P_{av}}{N'_0 W} = \alpha^2 \frac{\alpha^2}{6NN'_0} + \frac{N-1}{N} \frac{N'_0 + N''_0}{N'_0} (\alpha^2 - 1). \quad (16)$$

Figure 7 presents curves for the probability of error P_e vs. the coding delay N for $R/W = 0.2$ dit per cycle, and different values of the feedback noise relative to the forward noise, N''_0/N'_0 . For α^2 the value $\alpha^2 = 6N'_0$ as given by (11) is used. Hence, the curves present the degradation due to feedback noise of a system that is optimum for the noiseless feedback case.

III. CONCLUDING REMARKS

The WB (wideband) coding scheme, discussed in Part I, was suggested by the Robbins-Monro stochastic approximation procedure. In the Gaussian case it turns out that this coding procedure determines the maximum likelihood estimate of the message point θ recursively. Since the maximum likelihood estimate approaches 0

and the transmitted power is proportional to the square of the difference, the expected transmitted power per iteration decreases in this scheme. Retaining the maximum likelihood property but making up for the transmitted power in order to make the expected power per trans-

mission a constant, leads to the BL (band-limited) coding schemes. This simple scheme is the first deterministic procedure to achieve the channel capacity, $W \ln [1 + (P_{av}/N_0W)]$, of the band-limited white Gaussian noise channel.

It is believed that this approach of recursive maximum likelihood estimation to the coding problem with feedback has a much wider area of application, for example, channels with unknown parameters, fading channels, dependences between the noises in forward and feedback links, and so on. The method is ideally suited for noiseless feedback and it may well be possible to find an extension that is in some sense optimum for the noisy feedback case.

Coding for a Class of Unknown Channels

IRVIN G. STIGLITZ, MEMBER, IEEE

Abstract—A channel which is selected for each use (without knowledge of past history) to be one of a given set of discrete memoryless channels is to be used by an ignorant communicator, i.e., the transmitter and receiver are assumed to have no knowledge of the particular channels selected. For this situation an upper bound on the insurable average error probability for block codes of length n is obtained which exponentially approaches zero for all rates less than capacity. Communication design techniques for achieving these results are discussed.

FOR OUR PURPOSES, a statistically describable channel model is one for which the statistics of the channel output are known for each possible channel input. For a nonstatistically describable channel model, this statement does not hold.

The problem of designing communication systems for statistically describable channel models has been widely investigated. C. E. Shannon showed, for a large class of such models, that information can be transmitted over such a channel with arbitrarily small error probability for any rate less than a maximum rate called capacity.

For statistically describable discrete memoryless channel models, the minimum error probability, P_e , achievable with a block code of length n , has been overbounded for rates R less than capacity by [1], [2]

$$P_e \leq e^{-nE_1(R)} \quad (1)$$

where $E_1(R)$ is a function of the channel statistics and is a positive convex downward¹ function of R for R less than capacity.

The evaluation of capacity for a large class of nonstatistically describable channel models has been investigated by Blackwell, Breiman, and Thomasian [3], [4] and by Wolfowitz [5]. We investigate in the sequel the following class of discrete nonstatistically describable channel models. For each use the channel is selected in a fashion unknown to the transmitter or receiver to be one of a given fixed set of statistically describable channels. The channel selection mechanism is permitted to change from use to use; however, channels are assumed to be
