Abstract

We survey solution methods for the job shop scheduling problem with an emphasis on local search. We discuss both deterministic and randomized local search methods as well as the applied neighborhoods. We compare the computational performance of the various methods in terms of their effectiveness and efficiency on a standard set of problem instances.

Key words: job shop scheduling, local search, iterative improvement, shifting bottleneck heuristic, simulated annealing, taboo search, genetic algorithms, constraint satisfaction.

1 Introduction

In the job shop scheduling problem we are given a set of jobs and a set of machines. Each machine can handle at most one job at a time. Each job consists of a chain of operations, each of which needs to be processed during an uninterrupted time period of a given length on a given machine. The purpose is to find a schedule, that is, an allocation of the operations to time intervals on the machines, that has minimum length.

The problem is difficult to solve to optimality. For example, a relatively small instance with 10 jobs, 10 machines and 100 operations due to Fisher & Thompson [1963] remained unsolved until 1986. Many solution methods have been proposed, ranging from simple and fast dispatching rules to sophisticated branch-and-bound algorithms.

We survey algorithms for the job shop scheduling problem with an emphasis on local search. During the last decade many different types of local search algorithms for job shop scheduling have been developed, and some of them have proved to be very effective.

The paper is structured as follows. In Section 2 several models for the job shop scheduling problem are presented. In Section 3 the complexity of the problem and methods for its solution are reviewed. Section 4 introduces local search and Section 5 discusses representations and neighborhoods for the problem. Sections 6 and 7 describe constructive and iterative algorithms with local search, respectively; Section 8 describes some other techniques. Section 9 contains computational results, and Section 10 gives some concluding remarks.
2 The job shop scheduling problem

The job shop scheduling problem is formally defined as follows. Given are a set \( O \) of \( l \) operations, a set \( M \) of \( m \) machines, and a set \( J \) of \( n \) jobs. For each operation \( v \in O \) there is a processing time \( p(v) \in \mathbb{N} \), a unique machine \( M(v) \in M \) on which it requires processing, and a unique job \( J(v) \in J \) such that \( v \in J(v) \). On \( O \) a binary relation \( A \) is defined, which represents precedences between operations: if \( (v, w) \in A \), then \( v \) has to be performed before \( w \). \( A \) is such that all operations \( v \) with the same value \( J(v) \) are totally ordered.

A schedule is a function \( S : O \rightarrow \mathbb{N} \cup \{0\} \) that for each operation \( v \) defines a start time \( S(v) \). A schedule \( S \) is feasible if

\[
\forall v \in O : \quad S(v) \geq 0, \\
\forall v, w \in O, (v, w) \in A : \quad S(v) + p(v) \leq S(w), \\
\forall v, w \in O, v \neq w, M(v) = M(w) : \quad S(v) + p(v) \leq S(w) \text{ or } S(w) + p(w) \leq S(v).
\]

The length of a schedule \( S \) is \( \max_{v \in O} S(v) + p(v) \), i.e., the earliest time at which all operations are completed. The problem is to find an optimal schedule, i.e., a feasible schedule of minimum length.

A feasible schedule is left-justified, if no operation can start earlier without changing the processing order on any machine. It is active if no operation can start earlier without delaying another operation. Note that at least one optimal schedule is active and that each active schedule is left-justified.

An instance of the problem can be represented by means of a disjunctive graph \( G = (O, A, E) \) [Roy & Sussmann, 1964]. The vertices in \( O \) represent the operations, the arcs in \( A \) represent the given precedences between the operations, and the edges in \( E = \{(v, w) \mid v, w \in O, v \neq w, M(v) = M(w)\} \) represent the machine capacity constraints. Each vertex \( v \in O \) has a weight, equal to the processing time \( p(v) \).

For each \( E' \subseteq E \), an orientation on \( E' \) is a function \( \Omega : E' \rightarrow O \times O \) such that \( \Omega(\{v, w\}) \in \{(v, w), (w, v)\} \) for each \( \{v, w\} \in E' \); we write \( \Omega(E') = \{\Omega(e) \mid e \in E'\} \). A partial orientation is an orientation on \( E' \neq E \) and a complete orientation is one on \( E \). An orientation \( \Omega \) on \( E' \) is feasible if the digraph \( (O, A \cup \Omega(E')) \) is acyclic. It represents for each machine its machine ordering, i.e., the order in which it processes its operations. Each feasible schedule \( S \) uniquely determines a feasible complete orientation, which is denoted by \( \Omega_S \).

Conversely, for each feasible complete orientation \( \Omega \), there is a unique left-justified feasible schedule, which is denoted by \( S_\Omega \). For all \( v \in O \), \( S_\Omega(v) \) equals the length of a longest path in the digraph \( (O, A \cup \Omega(E)) \) up to and excluding \( v \). The length of \( S_\Omega \) equals the length of a longest path in the digraph. Finding an optimal left-justified schedule is now equivalent to finding a feasible complete orientation that minimizes the longest path length in the corresponding digraph.

The search for such a schedule can be restricted to the set of active schedules. However, given a feasible complete orientation \( \Omega \), it is not clear at first sight whether \( S_\Omega \) is active: activeness depends on the sizes of the processing times, while left-justifiedness does not. For this reason one often considers the larger set of left-justified schedules.

3 Complexity and algorithms

We give a brief review of results on the computational complexity of job shop scheduling, of the lower bounds and enumeration schemes that are used in branch-and-bound methods, and
of the approximative approaches that yield upper bounds on the optimum. Techniques of the latter type that proceed by local search are discussed in the rest of the paper.

### 3.1 Complexity

Some very special cases of the problem can be solved in polynomial time, but their immediate generalizations are NP-hard. The results are summarized in Table 1, where $l_j$ denotes the number of operations of the $j$th job. Note that, due to result (4b), it is NP-hard to find a job shop schedule that is shorter than $\frac{5}{4}$ times the optimum.

| (1a) $m = 2$, all $l_j \leq 2$ | (1b) $m = 2$, all $l_j \leq 3$; $m = 3$, all $l_j \leq 2$ |
| (2a) $m = 2$, all $p(v) = 1$ | (2b)* $m = 2$, all $p(v) \leq 2$; $m = 3$, all $p(v) = 1$ |
| (3a) $n = 2$ | (3b)* $n = 3$ |
| (4a) length $\leq 3$ | (4b)* length $\leq 4$ |

Table 1: The complexity of job shop scheduling

(1a) [Jackson, 1956]; (1b) [Lenstra, Rinnooy Kan & Brucker, 1977]; (2a) [Hefetz & Adiri, 1982]; (2b) [Lenstra & Rinnooy Kan, 1979]; (3a) [Akers, 1956; Brucker, 1988]; (3b) [Sotskov, 1991]; (4a,b) [Williamson, Hall, Hoogeveen, Hurkens, Lenstra & Shmoys, 1994].

### 3.2 Lower bounds

Optimization algorithms for the problem employ some form of tree search. A node in the tree is usually characterized by a partial orientation $\Omega$ on a subset $E' \subseteq E$. The question is then how to compute a lower bound on the length of any feasible schedule corresponding to a completion of $\Omega$.

Némethi [1964] and many subsequent authors obtained a lower bound by simply disregarding $E \setminus E'$ and computing the longest path length in the digraph $(O, A \cup \Omega(E'))$.

Bratley, Florian & Robillard [1973] obtained the stronger single-machine bound by relaxing the capacity constraints of all machines except one. Given a machine $M'$, they propose to solve the job shop scheduling problem on the disjunctive graph $(O, A \cup \Omega(E'), \{(v, w) \mid M'(v) = M'(w) = M') \setminus E')$. This is a single-machine problem, where the arcs in $A \cup \Omega(E')$ define release and delivery times for the operations on $M'$ and precedence constraints between them. Lageweg, Lenstra & Rinnooy Kan [1977] pointed out that many other lower bounds appear as special cases of this bound. For example, relaxing the capacity constraint of $M'$ gives Némethi's bound, and allowing preemption gives the bound used in current branch-and-bound codes. The bound itself is NP-hard to compute but can be found fairly efficiently [Baker & Su, 1974; McMahon & Florian, 1975; Lageweg, Lenstra & Rinnooy Kan, 1976; Carlier, 1982]. It has been strengthened by Carlier & Pinson [1990], who compute larger release and delivery times, and by Tiozzo [1988] and Dauzère-Perès & Lasserre [1993], who observe that the arcs also define delays between precedence-related operations.

Fisher, Lageweg, Lenstra & Rinnooy Kan [1983] investigated surrogate duality relaxations, in which either the machine capacity constraints or the precedence constraints among the operations of a job are weighted and aggregated into a single constraint. Balas [1985] described a first attempt to obtain bounds by polyhedral techniques. Applegate & Cook [1991] review the valid inequalities studied before and gave some new ones. The computational performance
of surrogate duality and polyhedral bounds reported until now is disappointing in view of what has been achieved for other hard problems.

3.3 Enumeration schemes

The traditional enumeration scheme generates all active schedules by constructing them from front to back [Giffler & Thompson, 1960]. At each node a machine on which the earliest possible completion time of any unscheduled operation is achieved is determined, and all unscheduled operations that can start earlier than this point in time on that machine are selected in turn.

Recent branch-and-bound algorithms use more flexible enumeration schemes. Carlier & Pinson [1989; 1990] and Applegate & Cook [1991] branch by selecting a single edge and orienting it in either of two ways. Brucker, Jurisch & Sievers [1994] follow Grabowski's 'block approach'. All these authors apply the preemptive single-machine bound and a host of elimination rules. For details we refer to the literature.

The celebrated $10 \times 10$ instance of Fisher & Thompson [1963] is within easy reach of these methods, but $15 \times 15$ instances seem to be the current limit. The main deficiency of the existing optimization algorithms for job shop scheduling is the weakness of the lower bounds. The situation is much brighter with respect to finding good upper bounds.

3.4 Upper bounds

Upper bounds on the optimum are usually obtained by generating a schedule and computing its length. An obvious first step is to apply a dispatch rule and to schedule the operations according to some priority function. Haupt [1989] surveys such rules. They tend to exhibit an erratic behaviour; the procedure 'bidir' proposed by Dell'Amico & Trubian [1993] is one of the safer alternatives. The next step is then to try to improve the schedule by some sort of local search.

An entirely different approach is taken by Sevast'janov [1994]. Using Steinitz' vector sum theorem, he develops polynomial-time algorithms for finding an upper bound with an absolute error that is independent of the number of jobs. Shmoys, Stein & Wein [1994] improve on his results.

4 Local search

Local search is based on the idea that a given solution may be improved by making small changes. Solutions are changed over and again, and better and better solutions are found.

We need the following notions. There is a set $F$ of feasible solutions. Two functions are defined on $F$. The cost function is a mapping $c : F \rightarrow \mathbb{R}$, which in most cases is closely related to the function that is to be optimized. The neighborhood function is a mapping $N : F \rightarrow 2^F$, which defines for each solution $x \in F$ a neighborhood $N(x) \subseteq F$. Each solution in $N(x)$ is called a neighbor of $x$. Roughly speaking, the execution of a local search algorithm defines a walk in $F$ such that each solution visited is a neighbor of the previously visited one.

A solution $x \in F$ is called a local minimum with respect to a neighborhood function $N$ if $c(x) \leq c(y)$ for all $y \in N(x)$. The basic algorithm to find a local minimum is called iterative improvement. Starting at some initial feasible solution, its neighborhood is searched for a
solution of lower cost. If such a solution is found, the algorithm is continued from there; otherwise, a local minimum has been found.

The quality of the local minimum depends on the initial solution, on the neighborhood function, and on the method of searching the neighborhoods. An initial solution may be obtained by generating it randomly or by applying a heuristic rule. The choice of a good neighborhood is often difficult. There is a clear trade-off between small and large neighborhoods: if the number of neighbors is larger, the probability of finding a good neighbor may be higher, but looking for it takes more time. There are several alternatives for searching the neighborhood: one may take the first neighbor found of lower cost (first improvement), or take the best neighbor in the entire neighborhood (best improvement), or take the best of a sample of neighbors, provided it is an improving one.

Often, one problem remains. The local optima obtained may be of poor quality. Therefore, several variants of iterative improvement have been proposed. The main variants can be divided into threshold algorithms, taboo search algorithms, and genetic algorithms.

In threshold algorithms, a neighbor of a given solution becomes the new current solution, if the cost difference between the current schedule and its neighbor is below a certain threshold. One distinguishes three kinds of threshold algorithms.

In classical iterative improvement the thresholds are 0, so that only true improvements are accepted. In threshold accepting [Dueck & Scheuer, 1990] the thresholds are nonnegative. They are large in the beginning of the algorithm's execution and gradually decrease to become 0 in the end. General rules to determine appropriate thresholds are lacking. In simulated annealing [Kirkpatrick, Gelatt & Vecchi, 1983; Černý, 1985] the thresholds are positive and stochastic. Their values equal \(-T \ln u\), where \(T\) is a control parameter (often called 'temperature'), whose value gradually decreases in the course of the algorithm's execution according to a 'cooling schedule', and \(u\) is drawn from a uniform distribution on \((0,1]\). Each time a neighbor is compared with the current solution, \(u\) is drawn again. Under certain mild conditions simulated annealing is guaranteed to find an optimal solution asymptotically.

In taboo search one selects from a subset of permissible neighbors of the current solution a solution of minimum cost. In basic taboo search a neighbor is permissible if it is not on the 'taboo list' or satisfies a certain 'aspiration criterion'. The taboo list is recalculated at each iteration. It is often implicitly defined in terms of forbidden moves from the current solution to a neighbor. The aspiration criterion expresses possibilities to overrule the taboo-status of a neighbor. For details see Glover [1989; 1990] or Glover, Taillard & De Werra [1993].

Genetic algorithms [Holland, 1975] are based on an extended notion of neighborhood function. A hyper-neighborhood function is a mapping \(N_h : F^s \to 2^F\) with \(s \geq 2\), which defines for each \(s\)-tuple \(x = (x_1, \ldots, x_s) \in F^s\) a set \(N_h(x) \subseteq F\) of neighboring solutions. Each solution in \(N_h(x)\) is called a hyper-neighbor of \(x\). At each iteration a set of solutions, often called 'population', is given. From this population several subsets of size \(s\) consisting of 'parents' are selected, and for each such subset some hyper-neighbors, called 'off-spring', are determined by operations called 'recombination' and 'mutation'. This set of hyper-neighbors and the current population are then combined and reduced to a new population by selecting a subset of solutions.

Several solution methods have been proposed that use local search in combination with other techniques like partial enumeration and backtracking. Such hybrid methods for job shop scheduling are dealt with below with an emphasis on nested forms of local search. Here, local search is applied at several levels with different neighborhoods. In this way the search can explore different regions of the solution space.
5 Solution representations and neighborhood functions

A crucial ingredient of a local search algorithm is the definition of a neighborhood function in combination with a solution representation. Below, several basic representations and neighborhood functions are introduced for the job shop scheduling problem. For most threshold and taboo search algorithms, only left-justified or active schedules are represented. This is done by specifying the start times of the operations or, equivalently, the corresponding machine orderings of the operations. Other representations are used too, especially in combination with genetic algorithms.

To be able to define the neighborhood functions, we need some extra notions. Given an instance and an operation \( v \), \( j(p(v)) \) and \( j(s(v)) \) denote the immediate predecessor and successor of \( v \) in the precedence relation \( A \), provided they exist. Given a feasible schedule \( S \) and an operation \( v \), \( m(p_S(v)) \) and \( m(s_S(v)) \) denote the immediate predecessor and successor of \( v \) in the orientation \( \Omega_S \), provided they exist. If the schedule \( S \) is clear from context, we delete the superscript \( S \). Furthermore, \( j(p^2(v)) \) denotes \( j(p(j(p(v)))) \), provided it exists, and a similar notation is used for \( j(s) \), \( m(p_S) \) and \( m(s_S) \). Two operations \( v \) and \( w \) are adjacent when \( S(v) + p(v) = S(w) \).

A block is a maximal sequence of size at least one, consisting of adjacent operations that are processed on the same machine and belong to a longest path. An operation of a block is internal if it is neither the first nor the last operation of that block.

Several neighborhood functions have been proposed in the literature. Most of these are not defined on a schedule \( S \) itself but on the corresponding orientation \( \Omega_S \). If \( \Omega_S \) is changed into another feasible orientation \( \Omega' \), \( S_{\Omega'} \) is the corresponding neighbor of \( S \). In this way neighbors of a given schedule are always left-justified.

The following properties [Balas, 1969; Matsuo, Suh & Sullivan, 1988; Nowicki & Smutnicki, 1993] are helpful in obtaining reasonable neighborhood functions.

1. Given a feasible orientation, reversing an oriented edge on a longest path in the corresponding digraph results again in a feasible orientation.
2. If reversing an oriented edge of a feasible orientation \( \Omega \) that is not on a longest path results in a feasible orientation \( \Omega' \), then \( S_{\Omega'} \) is at least as long as \( S_{\Omega} \).
3. Given a feasible orientation \( \Omega \), reversing an oriented edge \( (v, w) \) between two internal operations of a block results in a feasible schedule at least as long as \( S_{\Omega} \).
4. Given is a feasible orientation \( \Omega \). If \( v \) is the first and \( w \) the second operation of the first block of a longest path and \( w \) is internal, then reversing \( (v, w) \) results in a feasible schedule at least as long as \( S_{\Omega} \). The same is true if \( w \) is the last and \( v \) the second last operation of the last block of a longest path and \( v \) is internal.

In view of these properties, the simplest neighborhood functions are based on the reversal of exactly one edge of a given orientation. Van Laarhoven, Aarts & Lenstra [1992] propose a neighborhood function \( N_1 \) which obtains a neighbor by reversing two adjacent operations of a block. Matsuo, Suh & Sullivan [1988] use a neighborhood function \( N_{1a} \) with the same reversals, except those involving two internal operations. Nowicki and Smutnicki [1993] use a neighborhood function \( N_{1b} \), excluding from \( N_{1a} \) the reversal of the first two operations of the first block when the second one is internal and the reversal of the last two operations of the last block when the first is internal. For \( N_{1b} \), neither a schedule with one block only nor one with blocks of size one only has a neighbor; note that such schedules are optimal.

Dell’Amico & Trubian [1993] propose several neighborhood functions that may reverse more than one edge. Their neighborhood function \( N_2 \) obtains for any two operations \( v \) and \( w = m(s(v)) \) on a longest path a neighboring orientation by permuting \( m(p(v)) \), \( v \) and \( w \), or
by permuting \(v, w\) and \(ms(w)\), such that \(v\) and \(w\) are reversed and a feasible orientation results. Their neighborhood function \(N_{2\pi}\) excludes from \(N_2\) the solutions for which both \(v\) and \(w = ms(v)\) are internal. Their neighborhood function \(N_3\) considers blocks of size at least two: a neighbor is obtained by positioning an operation \(v\) immediately in front of or after the other operations of its block, provided that the resulting orientation is feasible; otherwise, \(v\) is moved to the left or the right as long as the orientation remains feasible.

Adams, Balas & Zawack [1988] propose a neighborhood function \(N_4\) which may completely change one machine ordering. For every machine \(M'\) with an operation on a longest path, a neighbor is obtained by replacing the orientation on \(M'\) by any other feasible orientation.

The following neighborhood functions obtain a neighbor by changing several machine orderings at the same time. Relatively small modifications are made by the neighborhood function \(N_5\) of Matsuo, Suh & Sullivan [1988], which reorients at most three edges simultaneously. A neighbor is obtained by reversing two adjacent operations \(v\) and \(w = ms(v)\) of a block (except when they are both internal) and in addition by reversing \(jp'\) for some \(t \geq 1\) and by reversing \(js(v)\) and \(ms(js(v))\). The latter reversals are executed only if certain additional conditions are satisfied; see their paper for details. Aarts, Van Laarhoven, Lenstra & Ulder [1994] use a variant \(N_{5\alpha}\), where \(t \leq 1\).

Applegate & Cook [1991] propose a neighborhood function \(N_6\) which drastically changes the given orientation. Their neighborhood contains all feasible orientations that can be obtained by simultaneously replacing the orientation on \(m - t\) machines by any other feasible orientation. Here, \(t\) is a small number depending on \(m\).

Storer, Wu & Vaccari [1992] use completely different representations of schedules. These are based on a modified version of the Giffler-Thompson algorithm (see Section 3.3). Suppose that at a certain point the earliest possible completion time of any unscheduled operation is equal to \(C\) and is achieved by operation \(v\), and that \(T\) is the earliest possible start time on machine \(M(v)\). Then all unscheduled operations on \(M(v)\) that can start no later than \(T + \delta(C - T)\) are candidates for the next position on \(M(v)\). Here, \(\delta\) is a priori chosen in \([0,1]\) (in experiments 0, 0.05 or 0.1); if \(\delta\) approaches 1 all active schedules can be generated, while \(\delta = 0\) gives only so-called non-delay schedules. Two representations are defined.

The representation \(R_7\) represents a schedule by modified processing times for the operations. Using these, the modified Giffler-Thompson algorithm with the shortest processing time rule as selection rule uniquely determines a feasible orientation \(\Omega\), and \(S_0\), computed with the original processing times, is the corresponding schedule. The neighborhood function \(N_7\) now obtains a neighbor by increasing the processing times by amounts of time that are independently drawn from a uniform distribution on \([-\theta, \theta]\). Here, \(\theta\) is a priori chosen (in experiments 10, 20 or 50). The representation \(R_8\) represents a schedule by dividing the scheduling horizon into several (in experiments 5, 10 or 20) time windows and assigning one of a given set of dispatch rules to each window. The modified Giffler-Thompson algorithm determines a schedule by applying the dispatch rule of the corresponding window. The neighborhood function \(N_8\) changes the dispatch rule for a window of a given schedule.

Genetic algorithms use two types of representations: the natural one, which is also used for most threshold and taboo search algorithms, and a more artificial one, using binary strings.

For the former type of representation Yamada & Nakano [1992] propose a hyper-neighborhood function \(N_{h1}\) which, given two schedules \(S\) and \(S'\), determines a neighbor using the Giffler-Thompson algorithm. When this algorithm has to choose from two or more operations, it takes, for a small \(\epsilon > 0\), the operation that is first in \(S\) with probability \(\frac{1+\epsilon}{2}\), the operation that is first in \(S'\) with probability \(\frac{1-\epsilon}{2}\), and a random operation from the other available
operations with probability \( \epsilon \).

Aarts, Van Laarhoven, Lenstra & Ulder [1994] propose a hyper-neighborhood function \( N_{h2} \). Given two schedules \( S \) and \( S' \), \( N_{h2} \) determines a neighbor by repeating the following step \( \left\lceil \frac{m}{2} \right\rceil \) times: choose a random arc \((w,v)\) of \( S' \) and change \( S \) by reversing arc \((v,w)\), provided it belongs to a longest path of \( S \).

The latter type of representation encodes a schedule or its orientation into a string over a finite - usually binary - alphabet. Such representations facilitate the application of hyper-neighborhood functions involving operations like 'crossover' and 'mutation'; see Goldberg [1989, pp. 166-175]. There are a number of drawbacks, however. A schedule or orientation may have several representatives, or none. Conversely, a string does not have to represent a schedule, and if it does, it may be nontrivial to calculate the corresponding schedule. Although attempts have been made to circumvent these difficulties, the hyper-neighborhood functions that operate on strings often have no meaningful effect in the context of the underlying problem. We will consider genetic algorithms using string representations in less detail.

6 Constructive algorithms with local search

In this section we discuss the shifting bottleneck procedure and its variants. These algorithms construct a complete schedule and apply local search to partial schedules on the way. A partial schedule is characterized by a partial orientation \( \Omega \) on a subset \( E' \subseteq E \). Its length is defined as the longest path length in the digraph \((O, A \cup \Omega(E'))\).

The basic idea of the algorithms described here is as follows. The algorithm goes through \( m \) stages. At each stage, it orients all edges between operations on a specific machine. In this way, at the beginning of any stage all edges related to some machines have been oriented, while the edges related to the other machines are not yet oriented. Furthermore, at the end of each stage, it applies iterative best improvement to the current partial schedule using neighborhood function \( N_4 \), which revises the orientation on a machine scheduled before. Orienting or reorienting the edges related to one machine in an optimal way requires the solution of a single-machine problem, where the partial schedule defines release and delivery times and delayed precedence constraints. The algorithms discussed hereafter mainly differ by the order in which the \( m \) machines are considered, by the implementation of iterative best improvement, and by the single-machine algorithm used.

The original shifting bottleneck procedure SBI of Adams, Balas & Zawack [1988] orients at each stage the edges related to the bottleneck machine. This is the unscheduled machine for which the solution value to the corresponding single-machine problem is maximum; the delays between precedence-related operations are not taken into account. After scheduling a machine, iterative best improvement is applied during three cycles. In each cycle each scheduled machine is reconsidered once. The first cycle handles the machines in the order in which they were sequenced. After a cycle is completed, the machines are reordered according to decreasing solution values to the single-machine problems in the last cycle. When all of the machines have been scheduled, the cycles continue as long as improvements are found. Furthermore, after a phase of iterative best improvement, the orientations on several machines that have no operations on a longest path are deleted, and then these machines are rescheduled one by one.

Applegate & Cook [1991] use almost the same algorithm. The main difference is that at
each stage iterative improvement cycles continue until no further improvements are found.

Dauzère-Peres & Lasserre [1993] were the first to take the delays between precedence-related operations into account. They develop a heuristic for the single-machine problem with delayed precedences and incorporate it into a shifting bottleneck variant.

Balas, Lenstra & Vazacopoulos [1994] develop an algorithm to solve the single-machine problem with delayed precedences to optimality, and use it to determine the bottleneck machine in their shifting bottleneck procedure SB3. Their local search strategy differs from the one of Adams, Balas & Zawack [1988] in some minor details; for instance, the number of cycles is limited to six. Again, after scheduling a new machine, they first apply iterative improvement, then delete the orientations on several non-critical machines, and reschedule these machines one by one. They also propose an extension SB4, which takes the best solution of SB3 and a variant of SB3 that reverses the order of the two reoptimizations procedures: first reschedule some non-critical machines, then apply regular iterative improvement. SB4 needs roughly twice the computation time of SB3 but finds several better schedules.

The shifting bottleneck procedure and its variants have been incorporated into other algorithms. Most of these employ some form of partial enumeration. Dorndorf & Pesch [1994] embed a variant in a genetic algorithm; see Section 7.3.

Adams, Balas & Zawack [1988] develop an algorithm SBII, which applies SBI to the nodes of a partial enumeration tree. A node corresponds to a subset of machines that have been scheduled in a certain way. In each of its descendants one more machine is scheduled. The schedule is obtained by first solving the single-machine problem, with release and delivery times defined by the parent node, and then applying iterative improvement as in SBI. Descendants are created only for a few machines with highest solution values to the single-machine problem. A penalty function is used to limit the size of the tree. For details about the branching rule, the penalty function and the search strategy we refer the reader to the original paper.

Applegate & Cook [1991] develop an algorithm Bottle-t, which employs partial enumeration in a different way. Bottle-t applies their shifting bottleneck variant described above as long as more than t machines are left unscheduled. For the last t machines it branches by selecting each remaining unscheduled machine in turn. The values t = 4, 5 and 6 were tested.

7 Iterative algorithms with local search

The algorithms presented in this section start from one or more given feasible schedules and manipulate these in an attempt to find better schedules. They can naturally be divided into threshold algorithms, taboo search algorithms, and genetic algorithms.

7.1 Threshold algorithms

The basic threshold algorithms are iterative improvement, threshold accepting, and simulated annealing. We also consider some closely related variants. Unless stated otherwise, a schedule is represented in the ordinary way by the starting times or the orientation.

Iterative improvement is the simplest threshold algorithm. Aarts, Van Laarhoven, Lenstra & Ulder [1994] test iterative improvement with the neighborhood functions $N_1$ and $N_{sa}$. To obtain a fair comparison with other algorithms they apply a multi-start strategy, i.e., they
run the algorithm with several randomly generated start solutions until a limit on the total running time is reached, and take the best solution found over all individual runs.

The algorithm Shuffle of Applegate & Cook [1991] uses the neighborhood function $N_6$. At each iteration, the schedule on a small number of heuristically selected machines remains fixed, and the schedule on the remaining machines is optimally revised by their branch-and-bound algorithm 'edge finder'. As initial solution they take the result of Bottle-5.

Storer, Wu & Vaccari [1992] propose a variant of iterative improvement, called PS10, with representation $R_7$ and neighborhood function $N_7$. Given a solution, a fixed number of neighbors (in experiments 100 or 200) is determined, the best one of which becomes the new solution. They also test a standard iterative first improvement algorithm, called HSL10, with representation $R_8$ and neighborhood function $N_8$. Neighbors are generated randomly and the algorithm stops after a fixed number of iterations (in experiments 1000 or 2000).

Threshold accepting has only been implemented by Aarts, Van Laarhoven, Lenstra & Ulder [1994]. Their algorithm TA1 uses the neighborhood function $N_1$. Threshold values are determined empirically.

Simulated annealing has been tested by several authors. Van Laarhoven, Aarts & Lenstra [1992] use the neighborhood function $N_1$. Aarts, Van Laarhoven, Lenstra & Ulder [1994] use $N_1$ (algorithm SA1) and $N_{5a}$ (algorithm SA2). Matsuo, Suh & Sullivan’s [1988] ‘controlled search simulated annealing’ algorithm CSSA is a bi-level variant, which also incorporates standard iterative improvement. Given a schedule $S$, a neighbor $S'$ is selected using the neighborhood function $N_5$. $S'$ is accepted or rejected by the simulated annealing criterion. In the latter case, $S'$ is subjected to iterative improvement using $N_5$ again, and if the resulting local optimum improves on $S$, it is accepted as the new solution. Their method also differs from most other implementations of simulated annealing in that the acceptance probability for a schedule that is inferior to the current schedule is independent of the difference in schedule length.

### 7.2 Taboo search algorithms

The taboo search algorithm TS1 of Taillard [1994] uses the neighborhood function $N_1$. After an arc $(v, w)$ has been reversed, the reversal of $w$ and its machine successor is put on the taboo list. Every 15 iterations a new length of the taboo list is randomly selected from a range between 8 and 14. The length of a neighbor is estimated in such a way that the estimate equals the length of the new schedule when both operations involved are still on a longest path, and that it is a lower bound otherwise. Then, from the permissible neighbors the schedule of minimum estimated length is selected as the new schedule.

The algorithm TS2 of Barnes & Chambers [1994] also uses $N_1$. Their taboo list has a fixed length. If no permissible moves exist, the list is emptied. The length of each neighbor is calculated exactly, not estimated. A start solution is obtained by taking the best from the active and non-delay schedules obtained by applying seven dispatch rules.

The algorithm TS3 of Dell’Amico & Trubian [1993] uses the union of the neighborhoods generated by $N_{2a}$ and $N_3$. The items on the taboo list are forbidden reorientations of arcs. Depending on the type of neighbor, one or more such items are on the list. The length of the list depends on the fact whether the current schedule is shorter than the previous one and the best one, or not. Furthermore, the minimal and maximal allowable lengths of the list are changed after a given number of iterations. When all neighbors are taboo and do not satisfy the aspiration criterion, a random neighbor is chosen as the next schedule. A start
solution is obtained by a procedure called 'bidir', which applies list scheduling simultaneously from the beginning and the end of the schedule, i.e., an operation is available when all of its predecessors or all its successors have been scheduled.

Nowicki & Smutnicki [1993] introduce an algorithm TSAB that combines taboo search with a backtracking scheme. In the taboo search part of their algorithm, the neighborhood function is a variant of $N_{1b}$, which only allows reorientations of arcs on a single longest path. The items on the taboo list are forbidden reorientations of arcs. The length of the list is fixed to 8. If no permissible neighbor exists, the following is done. If there is one neighbor only, which as a consequence is taboo, this one becomes the new schedule. Otherwise, the oldest items on the list are removed one by one until there is one non-taboo neighbor, and this one is chosen. A start solution is obtained by generating an active schedule using the shortest processing time rule or an insertion algorithm.

The backtracking scheme forces the taboo search to restart from promising situations encountered before. Suppose that at a certain point a new best schedule $S$ is found. Let $R(S)$ be the set of feasible arc reversals in $S$, let $T$ be the new taboo list, including the inverse of the reversal needed to obtain $S$, and let $r$ be the reversal that will be made in the next iteration. Then, if $|R(S)| \geq 2$, the triple $(S, R(S) \setminus \{r\}, T)$ is stored on a list. This list has a maximum length of 5; if it is full, the oldest triple is deleted before a new one is stored. Each time the taboo search algorithm stops (by reaching a maximum number of iterations without improving the best schedule), the backtracking scheme initiates a new round of taboo search starting from the schedule, the set of reversals and the taboo list of the last stored triple. When the set of reversals has one element only, the triple is deleted from the list; otherwise, it is replaced by the same triple with the reversal that will be made in the next iteration excluded. Note that during this new round new triples can be added to the list.

### 7.3 Genetic algorithms

The genetic algorithm GA1 of Yamada & Nakano [1992] determines for every chosen pair of schedules of the current population, two hyper-neighbors by using $N_{h1}$. From these four schedules two are selected for the next population: first the best schedule is chosen, and next the best unselected hyper-neighbor is chosen.

Aarts, Van Laarhoven, Lenstra & Ulder [1994] propose a genetic algorithm that incorporates iterative first improvement. In each iteration there is a population of solutions that are locally optimal with respect to either $N_1$ (algorithm GLS1) or $N_{sa}$ (algorithm GLS2). The population is doubled in size by applying $N_{h2}$ to randomly selected pairs of schedules of the population. Each hyper-neighbor is subjected to iterative first improvement, using $N_1$ or $N_{sa}$, and the extended population of local optima is reduced to its original size by choosing the best schedules. Then a next iteration is started. Start solutions are generated randomly, and iterative first improvement is applied to them before the genetic algorithm is started.

In the work of Davis [1985], Falkenauer & Bouffouix [1991] and Della Croce, Tadei & Volta [1994] a string represents for each machine a preference list, which defines a preferable ordering of its operations. From such a list a schedule is calculated. Davis [1985] and Falkenauer & Bouffouix [1991] restrict themselves to non-delay schedules; Della Croce, Tadei & Volta [1994] are able to represent other schedules as well. Falkenauer & Bouffouix [1991] and Della Croce, Tadei & Volta [1994] use the linear order crossover as hyper-neighborhood function. See the original papers for details.
Nakano & Yamada [1991] consider problem instances with exactly one operation for each job-machine pair. For each machine and each pair of jobs, they represent the order in which that machine executes those jobs by one bit. Thus, a schedule is represented by a string of $\frac{mn(n-1)}{2}$ bits. Since such a string may not represent a feasible orientation, they propose a method for finding a feasible string that is close to a given infeasible one. Two hyper-neighbors are obtained by cutting two strings at the same point and exchanging their left parts.

Dorndorf & Pesch [1994] propose a 'priority rule based genetic algorithm' P-GA, which uses the Giffler-Thompson algorithm. They use a string $(p_1, \ldots, p_{n-1})$, where $p_i$ is a dispatch rule that resolves conflicts in the $i$th iteration of the algorithm. Two hyper-neighbors are obtained by cutting two strings at the same point and exchanging their left parts. These authors also propose a second genetic algorithm, called SB-GA, which uses a shifting bottleneck procedure (see Section 6). A solution is represented by a sequence of the machines. A corresponding schedule is generated by a variant of SBI; each time it has to select an unoriented machine, it chooses the first unoriented machine in this sequence. The hyper-neighborhood function used is the cycle crossover; see Goldberg [1989, p. 175]. In contrast to SBI, reoptimization is applied only when less than six machines are left unscheduled.

8 Other techniques

8.1 Constraint satisfaction

Constraint satisfaction algorithms consider the decision variant of the job shop scheduling problem: given an overall deadline, does there exist a feasible schedule meeting the deadline? Most algorithms of this type apply tree search and construct a schedule by assigning start times to the operations one by one. A consistency checking process removes inconsistent start times of not yet assigned operations. If it appears that a partial schedule cannot be completed to a feasible one, a dead end is encountered, and the procedure has to undo several assignments. Variable and value ordering heuristics determine the selection of a next operation and its start time. The algorithm stops when a feasible schedule meeting the deadline has been found or been proved not to exist. Note that it is also possible to establish lower bounds on the optimum with this technique.

Sadeh [1991] developed an algorithm of this type, but its performance was poor. Nuijten, Aarts, Van Erp Taalman Kip & Van Hee [1993] improved it by designing new variable and value orderings and extensive consistency checking techniques. The resulting algorithm improved upon Sadeh's method in terms of both solution quality and speed, but still could not compete with the best job shop scheduling algorithms. The authors therefore modified their algorithm such that, when a dead end occurs, it restarts the search from the beginning, and they also randomized the selection of a next operation and its start time. Their 'randomized constraint satisfaction' algorithm RCS performs quite well.

8.2 Neural networks

Foo & Takefuji [1988a,b] describe a solution approach based on the deterministic neural network model with a symmetrically interconnected network, introduced by Hopfield & Tank [1985]. The job shop scheduling problem is represented by a 2-dimensional matrix of neurons. Zhou, Cherkassky, Baldwin, & Olson [1991] develop a neural network algorithm which uses a linear cost function instead of a quadratic one. For each operation there is one neuron in
the network, and also the number of interconnections is linear in the number of operations. The algorithm improves the results of Foo & Takefuji both in terms of solution quality and network complexity. Altogether, applications of neural networks to the job shop scheduling problem are at an initial stage, and the reported computational results are poor up to now.

9 Computational results

The computational merits of job shop scheduling algorithms have often been measured by their performance on the notorious 10 × 10 instance FT10 of Fisher & Thompson [1963]. Applegate & Cook [1991] found that several instances of Lawrence [1984] (LA21, LA24, LA25, LA27, LA29, LA38, LA40) pose a more difficult computational challenge. We have included the available computational results for these instances and, in addition, for two relatively easy instances (LA2, LA19) and for all remaining 15 × 15 instances of Lawrence (LA36, LA37, LA39). Each of these 13 instances has exactly one operation for each job-machine pair.

Tables 2 and 3 present the computational results for most algorithms discussed in Sections 6, 7 and 8, as far as these are available from the literature. Table 2 gives the schedule lengths obtained and Table 3 the corresponding running times.

In Table 2 the values UB and LB are the best known upper and lower bounds for the corresponding instances. For each method mentioned, a superscript b followed by a number x indicates that the results reported are the best ones obtained after x runs of the algorithm. If a superscript m occurs, the results reported are means over several runs. A superscript l indicates that the results reported are obtained by a single run. A hyphen denotes that no result is available. Furthermore, for each method and for each instance, we computed the relative error, i.e., the percentage that the best solution value found is above LB. For each algorithm, the values MRE and SRE are the mean relative error and the standard deviation of the relative error. Note that UB has already an MRE of 0.40.

Table 3 gives the CPU-times for the corresponding results of Table 2. If the result in Table 2 is a mean over several runs, the average CPU-time of a single run is given; if it is a best result over several runs, the total CPU-time is given. The value SCT is the sum of CPU-times over all instances; it was estimated if not all individual CPU-times were available. Also the computer used is mentioned. For each algorithm, the value CISCT is a computer-independent sum of CPU-times, computed using the work of Dongarra [1993].

Figure 1 shows for each algorithm the mean relative error and the corresponding computer-independent sum of CPU-times. Note that the time-axis has a logarithmic scale.

The shifting bottleneck procedure SBI of Adams, Balas & Zawack [1988] is fast but gives poor results. The variants SB3 and SB4 of Balas, Lenstra, & Vazacopoulos [1994], which take the delayed precedences into account, clearly give better results. The algorithm SBII of Adams, Balas & Zawack [1988], which uses partial enumeration, also improves upon SBI. Applegate & Cook [1991] obtain reasonable results with their algorithms Bottle-5 and Bottle-6. Note that the values given in Tables 2 and 3 do not correspond to those presented in their paper. We computed our values using the enumeration scheme described in their paper; their values were obtained using a different scheme [Applegate & Cook, 1993]. The results suggest that the straight shifting bottleneck procedure (as in SBI, SB3 and SB4) benefits from some form of partial enumeration (as in SBII and Bottle-t).

Among threshold algorithms the best results are obtained by the simulated annealing

Table 3: Performance comparison of various algorithms: computation times for 13 instances
Figure 1: Relation between mean relative error and computer independent sum of CPU-times

Regarding iterative improvement, Aarts, Van Laarhoven, Lenstra & Ulcer [1994] report that their multi-start algorithm is inferior to threshold accepting and simulated annealing. Applegate & Cook's Shuffle algorithm works well, due to a neighborhood function that allows major changes in the schedule. We used our own outcomes of Bottle-5 as start solutions. The number of machines to fix was chosen such that edge finder could rapidly fill in the remainder of the schedule. We set $t=1$ for the instances FT10, LA2 and LA19, $t=2$ for LA21, LA24 and LA24, and $t=5$ for the other instances. The results for these values of $t$ are reported under Shuffle1. We also carried out some more time consuming runs with $t=1$ for FT10 and LA2-LA24, $t=3$ for LA29, LA36 and LA37, and $t=4$ for LA27, LA38, LA39 and LA40. The outcomes, reported under Shuffle2, are good but expensive.

Storer, Wu, & Vaccari [1992] give very few computational results for their variants of iterative improvement. Their results for the instance FT10 are poor. It seems that their search strategy or their neighborhood function is not powerful enough.

The threshold accepting algorithm of Aarts, Van Laarhoven, Lenstra & Ulcer [1994] competes with their simulated annealing algorithm in case simulated annealing finds an optimal schedule. Otherwise, threshold accepting is outperformed by simulated annealing. Almost all instances in our table belong to the latter category.

The simulated annealing algorithm of Van Laarhoven, Aarts & Lenstra [1992] produces reasonable results. Five runs on FT10 with a standard setting of the cooling parameters produced an average schedule length of 985.8, with a minimum of 951; a much slower cooling schedule yields solution values of 930 (twice), 934, 935 and 938. Reasonable results are also obtained by the simulated annealing algorithm of Aarts, Van Laarhoven, Lenstra & Ulcer [1994] with a standard cooling schedule, but an extremely slow cooling schedule gives very good results. To compute MRE and SRE for the latter cooling schedule, we estimated the values for the missing entries. It is remarkable that their algorithm with the standard cooling schedule has a similar behaviour for the neighborhood functions $N_1$ (SA1) and $N_{sa}$ (SA2). Good results are obtained by the simulated annealing variant CSSA of Matsuo, Sun, & Sullivan [1988]. In comparison to other approximative approaches, simulated annealing may require large running times, but it yields consistently good solutions with a modest amount of human implementation effort and relatively little insight into the combinatorial structure of the problem type under consideration.

The advent of taboo search has changed the picture. Methods of this type produce excellent solutions in reasonable times, although these benefits come at the expense of a non-trivial amount of testing and tuning. Although few data are available, Taillard's [1994] algorithm TS1 seems to perform extremely well. Also very good results are obtained by algorithm TS2 of Barnes & Chambers [1991]. Dell'Amico & Trubian's [1993] algorithm TS3 obtained even better results. Apparently, their complicated neighborhood function is very effective. The algorithm TSAB of Nowicki & Smutnicki [1993], which applies taboo search and traces its way back to promising but rejected changes, is the current champion for job shop scheduling. For our 13 instances it achieves a mean relative error of only 0.54 %.

For many genetic algorithms no results for our 13 instances are available. Sometimes, only the result for FT10 is given. Yamada & Nakano [1992] found a schedule of length 930 four times among 600 trials. They also tested their algorithm GA1 on four 20-job 20-machine instances, but their outcomes are on average 5.9 % above the best known upper bounds [Wennink, 1994]. The results obtained by Aarts, Van Laarhoven, Lenstra & Ulcer [1994] are
not very strong. Their algorithm GLS2 (using neighborhood function $N_{sa}$) performs slightly better than GLS1 (using $N_1$).

As for genetic algorithms using string representations, the results obtained by Della Croce, Tadei, & Volta’s [1994] algorithm GA2 and by Nakano & Yamada’s [1991] algorithm GA3 are poor. The algorithm P-GA of Dorndorf & Pesch [1994] is even worse. Their algorithm SB-GA, which incorporates a shifting bottleneck variant, produces reasonable results. Values are reported for runs with population sizes of 40 and 60.

The constraint satisfaction algorithm of Nuijten, Aarts, Van Erp Taalman Kip & Van Hee [1993] produces good results but needs a lot of time. For the neural network approaches no computational results are available that allow a proper comparison with other techniques.

10 Conclusion

10.1 Review

Current optimization algorithms for job shop scheduling can handle problem instances no harder than the $15 \times 15$ instances of Lawrence in reasonable amounts of running time. If one wants to obtain approximate solutions to larger instances, one has to resort to local search.

From the local search algorithms discussed in this survey, taboo search seems to work best. For the 13 instances investigated, the algorithm of Nowicki & Smutnicki, which combines taboo search with backtracking, outperforms the other local search algorithms developed so far. Also the implementations of taboo search by Dell’Amico & Trubian and of simulated annealing by Aarts, Van Laarhoven, Lenstra, & Ulder perform very well, but the latter only if large running times are allowed.

The various shifting bottleneck procedures produce schedules of moderate quality. Better results are obtained in combination with some type of local search or backtracking.

Genetic algorithms have a poor performance until now. Often the neighborhood function applied in combination with the schedule representation chosen does not generate meaningful changes and it is hard to find improvements. Only when some kind of standard local search is embedded at a second level, the computational results are satisfactory.

10.2 Preview

There is still considerable room for improving local search approaches to the job shop scheduling problem. As shown in Figure 1, none of the existing algorithms achieves an average error of less than 2% within 100 seconds. And our benchmark instances are still small ones.

We have observed that many approaches operate at two levels, with, for instance, schedule construction, partial enumeration or local search with big changes at the top level, and local search with smaller changes at the bottom level. Such hybrid approaches are in need of a more systematic investigation. The type of backtracking proposed by Nowicki & Smutnicki is a promising technique and can be combined with almost any local search algorithm without difficulties. It might also be interesting to design a three-level approach with neighborhoods of smaller size towards the bottom.

The flexibility of local search and the results reported here provide a promising basis for the application of local search to more general scheduling problems. An example of practical interest is the multiprocessor job shop, where each production stage has a set of parallel
machines rather than a single one. Finding a schedule involves assignment as well as sequencing decisions. This is a difficult problem, for which no effective solution methods exist.

Applying local search to large instances of scheduling problems requires the design of data structures that allow fast incremental computations of, for example, longest paths. Johnson [1990] has shown that sophisticated data structures play an important role in the application of local search to large traveling salesman problems.

Our survey has been predominantly of a computational nature. There are several related theoretical questions about the complexity of local search. A central concept in this respect is PLS-completeness [Johnson, Papadimitriou, & Yannakakis, 1988]. Many of the neighborhood functions defined in Section 5 define a PLS-problem, which may be PLS-complete. There are also complexity issues regarding the parallel execution of local search. For example, for some of the neighborhood functions it may be possible to verify local optimality in polylog parallel time.
