Keywords
CO₂ hydrogenation, low-pressure process, Cu/Zn catalyst, H₂ stripping, energy efficiency

Highlights
- Efficient process for methanol synthesis by hydrogenation of carbon dioxide
- Stripping of products with wet hydrogen for double positive effect
- Minimum consumption of raw materials, and limited use of electricity and steam

Abstract
Methanol is an alternative fuel that offers a convenient solution for efficient energy storage. Complementary to carbon capture activities, significant effort is devoted to the development of technologies for methanol synthesis by hydrogenation of carbon dioxide. While CO₂ is available from plenty of sources, cheap sources of H₂ are less frequently found. An additional source of hydrogen at industrial scale is the wet hydrogen by-product of chlorine production. This study is the first to propose an efficient process for methanol synthesis by CO₂ hydrogenation using wet hydrogen by-product from chlor-alkali production. A key feature of this novel process is the use of a stripping unit where the wet hydrogen flows in counter-current mode with the condensed methanol-water mixture resulting from the high-pressure low-temperature separator after the reaction. This operation has a double positive effect, as it removes the CO/CO₂ from the methanol-water mixture thus allowing a complete recycle of CO₂ and avoiding its presence in the product, while also removing the water from the wet hydrogen thus avoiding the negative impact of adding water on the equilibrium conversion – with consumption figures of 550 kWh electricity and 0.48-1.16 ton steam per ton methanol.
1. Introduction

Methanol is a viable alternative energy source, offering a convenient solution for the efficient energy storage on a large scale, while playing an important role in economy and sustainability by converting the CO$_2$ waste from industry into a valuable product (Olah et al., 2009). At industrial scale, methanol is produced from synthesis gas (CO/CO$_2$/H$_2$) using various catalysts based on CuO/ZnO/Al$_2$O$_3$. Complementary to carbon capture and sequestration (CCS), much effort is being put on the development of technologies for methanol production from carbon dioxide. Several review papers published during the past decade cover this topic very well.

Liu et al. (2003) reviewed the progress in the catalyst innovation, optimization of the reaction conditions, reaction mechanism, and catalyst performance in CO and CO$_2$ hydrogenation to methanol, highlighting the key issues of catalyst improvement and areas of priority in R&D. Centi and Perathoner (2009) analyzed the possibilities of converting CO$_2$ to fuels, noting that the requisites for this objective are: minimization of the consumption of hydrogen (sources), production of fuels that can be easily stored and transported, and the use of renewable energy sources. Their review included CO$_2$ reverse water-gas shift (WGS) and hydrogenation to hydrocarbons, alcohols, dimethyl ether or formic acid, as well as the reaction to synthesis gas; photo- and electrochemical/catalytic conversion; and thermo-chemical conversion.

Kondratenko et al. (2013) discussed the heterogeneously catalyzed hydrogenation, as well as the photocatalytic and electrocatalytic conversion of CO$_2$ to hydrocarbons or oxygenates, along with the design of electrodes to improve their performance and the recent developments of the application of ionic liquids as electrolytes and of microorganisms as co-catalysts.

Saeidi et al. (2014) focused on hydrocarbon and methanol synthesis as methods to convert CO$_2$ to value-added products. The reaction mechanisms as well as the effects of catalyst, reactor type and operating conditions on product efficiency enhancement of each process were reviewed. Also a brief overview on the reactor types and configurations was provided.

Yan et al. (2014) concentrated on the recent advances in designing efficient catalysts for the hydrogenation of CO$_2$ to fuels, e.g. CO$_2$ hydrogenation to methanol, CO$_2$ conversion to CO via reverse WGS reaction and production of hydrocarbons through Fischer-Tropsch synthesis.

Jadhav et al. (2014) tackled various aspects on the CO$_2$ hydrogenation reaction system such as: thermodynamics, innovations in catalysts, influences of reaction variables, overall catalyst performance, reaction mechanism and kinetics, and recent technological advances.

While plenty of CO$_2$ is available from CCS activities, flue gas or as by-product in various processes (e.g. bioethanol production), the sources of hydrogen are more limited but feature processes such as steam methane reforming, coal gasification, partial oxidation of light oil
residues, dry reforming, water electrolysis, sulfur-iodine or copper chloride processes (Jadhav et al., 2014). Another major industrial source is the chlor-alkali process, where H₂ is formed as by-product of the salt electrolysis. Based on stoichiometry, 1 ton of chlorine leads to 28 kg hydrogen that can be further converted into 149 kg methanol, using 205 kg CO₂.

This article is the first to propose an efficient process for the CO₂ conversion to methanol using wet hydrogen (saturated with water) from brine electrolysis, in a catalytic process based on highly active Cu/Zn/Al/Zr fibrous catalyst (Kiss et al., 2013). For convenience, the results are provided for a 100 ktpy methanol plant, rigorously simulated in Aspen Plus and including experimental data previously reported in literature (An et al., 2009).

2. Problem statement
Methanol synthesis requires efficient chemical processes and inexpensive raw materials. Converting carbon dioxide to methanol by hydrogenation is considered to be a great industrial opportunity (Olah et al., 2009). While cheap CO₂ is available from many sources, the options for low-cost hydrogen are rather limited. An interesting option is the use of wet hydrogen available as by-product in the chlor-alkali production. The issue is that the direct use of water saturated hydrogen stream has a strong negative impact on the chemical equilibrium. To solve this issue, an efficient process is proposed that includes a key feature – namely the use of stripper that has a double positive effect as it removes the CO₂ from the methanol-water mixture produced and avoids the presence of CO/CO₂ in the products, while also removing the water from the wet hydrogen feed initially saturated with water. The efficiency of the process is thus increased, leading to low consumption figures.

3. Process simulation
This section presents the main results for a plant producing 100 ktpy methanol, by CO₂ hydrogenation using a highly active Cu/Zn/Al/Zr fibrous catalyst (An et al., 2009).

3.1 Property model
The complete process was rigorously simulated in Aspen Plus using the RK-Soave property model which is most suitable for these components (H₂, CO, CO₂, H₂O, and CH₃OH) and conditions (pressure up to 50 bar and temperature up to 250 °C). The non-random two-liquid (NRTL) model was used complementary to the RK-Soave property model, for modeling the distillation section operating at low pressure and in which no hydrogen is present. This is in line with literature recommendations for such systems (Kiss, 2013; Dimian et al., 2014). Note
that all the binary interaction parameters related to the property models RK-Soave and NRTL are available in the pure components databank of the Aspen Plus process simulator.

3.2 Chemical reactions

The pathways for methanol formation from CO₂/CO and H₂ on a metallic Cu catalyst are given in Kondratenko et al. (2013). The actual chemistry of CO₂ hydrogenation involves three main equilibrium reactions (A, B and C) leading to methanol and water (Fiedler et al., 2005):

A) \( \text{CO} + 2 \text{H}_2 \rightleftharpoons \text{CH}_3\text{OH} \quad \Delta H_{298K} = -90.77 \text{ kJ/mol} \) (1)

B) \( \text{CO}_2 + \text{H}_2 \rightleftharpoons \text{CO} + \text{H}_2\text{O} \quad \Delta H_{298K} = +41.21 \text{ kJ/mol}, \text{Reverse WGS reaction} \) (2)

C) \( \text{CO}_2 + 3 \text{H}_2 \rightleftharpoons \text{CH}_3\text{OH} + \text{H}_2\text{O} \quad \Delta H_{298K} = -49.16 \text{ kJ/mol} \) (3)

The CO₂ conversion to CO (reaction B) is endothermic hence the temperature increase is favorable to the equilibrium. However, the CO and CO₂ conversions to methanol (reactions A and C) are exothermic hence the temperature increase has a negative impact on equilibrium. Thus, higher methanol yields are obtained at lower temperatures and higher pressures. This effect is clearly illustrated in Figure 1 showing the effect of temperature on equilibrium.

Note that in a process having all three components (CO₂, CO, and H₂) in the feed, the mole fractions have to be adjusted such that the optimal stoichiometric number (SN) is equal to 2. A higher value (SN > 2) indicates that there is an excess of H₂ in the feed gas, while a lower value (SN < 2) means that there is an excess of carbon. When only CO₂ and H₂ are present in the feed, a H₂:CO₂ ratio of 3:1 ensures that SN=2. The SN number is calculated as follows:

\[ SN = \frac{y_{\text{H}_2} - y_{\text{CO}_2}}{y_{\text{CO}} + y_{\text{CO}_2}} \] (4)

3.3 Chemical equilibrium

The values for the equilibrium constants (\( K_A \), \( K_B \) and \( K_C \)) were reported by Lim et al. (2009), using \( R=8.314 \text{ J/mol.K} \) and \( K_i \). Note that the study of Lim et al. (2009) used the experimental data from Graaf et al. (1986), so basically it is the same data but provided in an explicit model which provides a consistent framework for process simulations in Aspen Plus.

The comparison between the data from literature (Lim et al. 2009) and the equilibrium constant values evaluated within Aspen Plus using the equilibrium reactor showed an excellent agreement. Note that in Aspen Plus, the equilibrium constants are evaluated based
upon fugacity in [atm]. A conversion was made to [Pa] based correlations as those will be required to express the driving force term of the kinetic rate equations.

\[
\ln K_A = \frac{9.8438 \times 10^4}{RT} - 29.07 \Rightarrow K_A = 2.3717 \times 10^{-13} \exp\left(\frac{9.8438 \times 10^4}{RT}\right) \text{[atm}^{-2}]\text{]}
\]

\[
\ln K_A = -52.096 + \frac{11840}{T} \quad \text{with } K_A \text{ [Pa}^{-2}]\text{] (5)
\]

\[
\ln K_B = -\frac{4.3939 \times 10^4}{RT} + 5.639 \Rightarrow K_B = 2.8118 \times 10^2 \exp\left(-\frac{4.3939 \times 10^4}{RT}\right) \text{[-]}
\]

\[
\ln K_B = 5.639 + \frac{-5285}{T} \quad \text{with } K_B \text{ [-]} (6)
\]

\[
K_C = K_A \times K_B \Rightarrow K_C = 6.6688 \times 10^{-11} \exp\left(\frac{5.4499 \times 10^4}{RT}\right) \text{[atm}^{-2}]\text{]}
\]

\[
\ln K_C = -46.457 + \frac{6555}{T} \quad \text{with } K_C \text{ [Pa}^{-2}]\text{] (7)
\]

3.4 Catalyst and kinetics

Many catalysts are available for CO₂ hydrogenation, based on Cu/Zn formulations (Yan et al., 2014). Also most of the commercial catalysts available from several catalyst manufacturers (e.g. Katalko from Johnson-Matthey, MegaMax from Clariant) have high performance. In this work, the kinetic model A3B2C3 – which was shown to be the best kinetic model out of the 48 models tested by Graaf et al. (1988) – combined with kinetic data from An et al. (2009) was implemented in Aspen Plus. Note that other adequate kinetic models are also available in the literature (Bos et al. 1989; Vanden Bussche and Froment 1996; Coteron and Hayhurst, 1994; and numerous publications from Haldor Topsoe).

The experimental data from An et al. (2009) validates the model of Graaf et al (1988) and it was obtained for a fibrous Cu/Zn/Al/Zr catalyst that was designed especially for the hydrogenation of CO₂. Note that the Langmuir-Hinshelwood kinetic model assumes two different active sites. CO and CO₂ absorb competitively on the so called s1-sites, while H₂ and H₂O are absorbed competitively on the s2-sites. According to Graaf et al. (1988) the adsorption of methanol is assumed to be negligible, while H₂ is believed to adsorb dissociatively – hence the use of \( \lambda_H \) term. Nonetheless, it is rather straightforward to derive alternative kinetic rate expressions that are based on the molecular adsorption of H₂. The elementary reactions are described as follows (Graaf et al., 1988):
Adsorption equilibria

1. \( \text{CO} + \text{s1} = \text{COs1} \) \hspace{1cm} (8)
2. \( \text{CO}_2 + \text{s1} = \text{CO}_2\text{s1} \) \hspace{1cm} (9)
3. \( \text{H}_2 + 2\text{s2} = 2\text{Hs2} \) \hspace{1cm} (10)
4. \( \text{H}_2\text{O} + \text{s2} = \text{H}_2\text{Os2} \) \hspace{1cm} (11)

Reaction (A)

5. \( \text{COs1} + \text{Hs2} = \text{HCOs1} + \text{s2} \) \hspace{1cm} (12)
6. \( \text{HCOs1} + \text{Hs2} = \text{H}_2\text{COs1} + \text{s2} \) \hspace{1cm} (13)
7. \( \text{H}_2\text{COs1} + \text{Hs2} = \text{H}_3\text{COs1} + \text{s2} \) \hspace{1cm} (14)
8. \( \text{H}_3\text{COs1} + \text{Hs2} = \text{CH}_3\text{OH} + \text{s1} + \text{s2} \) \hspace{1cm} (15)

Reaction (B)

9. \( \text{CO}_2\text{s1} + \text{Hs2} = \text{HCO}_2\text{s1} + \text{s2} \) \hspace{1cm} (16)
10. \( \text{HCO}_2\text{s1} + \text{Hs2} = \text{COs1} + \text{H}_2\text{Os2} \) \hspace{1cm} (17)

Reaction (C)

11. \( \text{CO}_2\text{s1} + \text{Hs2} = \text{HCO}_2\text{s1} + \text{s2} \) \hspace{1cm} (18)
12. \( \text{HCO}_2\text{s1} + \text{Hs2} = \text{H}_2\text{CO}_2\text{s1} + \text{s2} \) \hspace{1cm} (19)
13. \( \text{H}_2\text{CO}_2\text{s1} + \text{Hs2} = \text{H}_3\text{CO}_2\text{s1} + \text{s2} \) \hspace{1cm} (20)
14. \( \text{H}_3\text{CO}_2\text{s1} + \text{Hs2} = \text{H}_2\text{COs1} + \text{H}_2\text{Os2} \) \hspace{1cm} (21)
15. \( \text{H}_2\text{COs1} + \text{Hs2} = \text{H}_3\text{COs1} + \text{s2} \) \hspace{1cm} (22)
16. \( \text{H}_3\text{COs1} + \text{Hs2} = \text{CH}_3\text{OH} + \text{s1} + \text{s2} \) \hspace{1cm} (23)

In case of the best model concluded by Graaf et al. (1988) the rate controlling steps for each overall reaction A, B and C are A3, B2, and C3 respectively – hence the notation A3B2C3.

The corresponding rate equations for the kinetic model A3B2C3 are:

\[
r_{\text{CH}_3\text{OH},A3} = k_A \frac{f_{\text{CO}} f_{\text{H}_2}^{3/2} - f_{\text{CH}_3\text{OH}}}{(1 + K_{\text{CO}} f_{\text{CO}} + K_{\text{CO}_2} f_{\text{CO}_2}) \left( f_{\text{H}_2} + (K_{\text{H}_2,0} / \sqrt{K_{\text{H}_2}}) f_{\text{H}_2,0} \right)}
\] \hspace{1cm} (24)

\[
r_{\text{CO},B2} = r_{\text{H},0,B2} = k_B \frac{f_{\text{CO}_2} f_{\text{H}_2} - f_{\text{H},0} f_{\text{CO}}}{(1 + K_{\text{CO}} f_{\text{CO}} + K_{\text{CO}_2} f_{\text{CO}_2}) \left( f_{\text{H}_2} + (K_{\text{H}_2,0} / \sqrt{K_{\text{H}_2}}) f_{\text{H}_2,0} \right)}
\] \hspace{1cm} (25)
For example, the origin of $r_{\text{CH}_3\text{OH},A_3}$ is explained hereafter.

$$r_{\text{CH}_3\text{OH},A_3} = r_{H,O,C_3} = k_c \frac{K_{\text{CO}_2} \left[f_{\text{CO}_2} f_{H_2} \frac{3}{2} - f_{H,O} f_{\text{CH}_3\text{OH}} \ln(f_{H_2} \frac{3}{2} K_c) \right]}{\left(1 + K_{\text{CO}_2} f_{\text{CO}_2} + K_{\text{CO}_2} f_{\text{CO}_2} \right) \left[f_{H_2} + \left(K_{H,O} \sqrt{K_H} f_{H,O} \right) \right]}$$  \quad (26)

Therefore:

$$\theta_{H,CO} = K_{A_1} K_{A_2} \left(\frac{\lambda_H}{\lambda_c}\right)^2 \theta_{CO} = K_{A_1} K_{A_2} K_H f_{H_2} \theta_{CO}$$  \quad (29)

As a result it follows that:

$$r_{A_3} = k_{A_3} K_{A_1} K_{A_2} \frac{K_{\text{CO}_2} f_{\text{CO}_2} \left(f_{H_2} \frac{3}{2} - f_{\text{CH}_3\text{OH}} \ln(f_{H_2} \frac{3}{2} K_c) \right)}{\left(1 + K_{\text{CO}_2} f_{\text{CO}_2} + K_{\text{CO}_2} f_{\text{CO}_2} \right) \left[f_{H_2} + \left(K_{H,O} \sqrt{K_H} f_{H,O} \right) \right]}$$  \quad (31)

The equilibrium constant of the overall reaction (A) is used to define the driving force term:

$$K_A = \frac{f_{\text{CH}_3\text{OH}}}{f_{\text{CO}_2} f_{H_2}^{\frac{3}{2}}} \quad \text{Driving force} = f_{\text{CO}_2} f_{H_2}^{\frac{3}{2}} - f_{\text{CH}_3\text{OH}} \ln(f_{H_2} \frac{3}{2} K_c)$$  \quad (32)

Thus:

$$r_A = r_{A_3} - r_{A_1} = k_{A_3} K_{A_1} K_{A_2} \frac{K_{\text{CO}_2} K_H \left(f_{\text{CO}_2} f_{H_2} \frac{3}{2} - f_{\text{CH}_3\text{OH}} \ln(f_{H_2} \frac{3}{2} K_c) \right)}{\left(1 + K_{\text{CO}_2} f_{\text{CO}_2} + K_{\text{CO}_2} f_{\text{CO}_2} \right) \left[f_{H_2} + \left(K_{H,O} \sqrt{K_H} f_{H,O} \right) \right]}$$  \quad (33)

According to Graaf et al. (1988) it holds:

$$1 << \sqrt{K_H f_{H_2} + K_{H,O} f_{H,O}}$$  \quad (34)

Comparing this with the result presented by Eq. 43 in Graaf et al. (1988), it is concluded that:

$$k_A = k_{A_3} K_{A_1} K_{A_2} K_H$$  \quad (36)

The origin of the other terms ($r_{\text{CO},B_2}$ and $r_{\text{CH}_3\text{OH},C_3}$) can be explained in a similar way.

The generalized rate expression to be used in Aspen Plus is given by:

$$r = \frac{\text{(kinetic factor)(driving force expression)}}{\text{(adsorption term)}}$$  \quad (37)

When a reference temperature $T_o$ is not specified, the kinetic factor in Aspen is expressed by a
pre-exponential factor and an Arrhenius term: \(\text{kinetic factor} = kT^n \exp(-E_a/RT)\). All the
required input data for the kinetic factor are included in Table 1 (An et al., 2009). Note that
the units for the pre-exponential constant depend on the units of the driving force term and the
adsorption term. Therefore the units are not the same for all of the reactions.

The driving force expressions are as follows:

Reaction A: \(K_{CO}f_{CO}f_{H_2}^{3/2} - \frac{K_{CO}}{K_A}f_{CH_4,OH}f_{H_2}^{-1/2} \quad [Pa^{3/2}]\) \hspace{1cm} (38)

Reaction B: \(K_{CO}f_{CO}f_{H_2} - \frac{K_{CO}}{K_B}f_{H_2,O}f_{CO} \quad [Pa]\) \hspace{1cm} (39)

Reaction C: \(K_{CO}f_{CO}f_{H_2}^{3/2} - \frac{K_{CO}}{K_C}f_{H_2,O}f_{CH_4,OH}f_{H_2}^{-3/2} \quad [Pa^{3/2}]\) \hspace{1cm} (40)

Note that in Aspen Plus, the driving force is expressed in a generalized form:

\[K_i\left(\prod c_i^{n_i}\right) - K_2\left(\prod c_j^{n_j}\right)\] \hspace{1cm} (41)

When selecting the vapor phase as the reactive phase, and neglecting the difference between
partial pressure and fugacity (i.e. assuming ideal gas), the partial pressures are used for the
concentration. The resulting values for \(K_i\) and \(K_2\) are given in Table 2. In Aspen Plus, \(K_i\) and
\(K_2\) are expressed in a logarithmic form, so the resulting input parameters are given in Table 3.

\[\ln(K) = A + \frac{B}{T}\] \hspace{1cm} (42)

The adsorption term is the same for all reactions. The expression applied in Aspen Plus is:

\[\left(\sum K_i\left[\prod c_i^{n_i}\right]\right)^n\] \hspace{1cm} (43)

Configuring Aspen Plus requires re-writing the adsorption term in the kinetic expression,
which is the same for all three reactions (Graaf et al., 1988):

\[\left(1 + K_{CO}f_{CO} + K_{CO}f_{CO}^{1/2} + \left[K_{H_2,O}/\sqrt{K_H}\right]f_{H_2,O}\right)[bar^{1/2}] = \] \hspace{1cm} (44)

\[\sqrt{f_{H_2} + \frac{K_{H_2,O}}{\sqrt{K_H}}f_{H_2,O} + K_{CO}f_{CO}^{1/2}f_{H_2,O} + \frac{K_{CO}K_{H_2,O}}{\sqrt{K_H}}f_{CO}f_{H_2,O} + K_{CO}f_{CO}^{1/2}f_{H_2,O} + \frac{K_{CO}K_{H_2,O}}{\sqrt{K_H}}f_{CO}f_{H_2,O}}\]

Both the numerator and the denominator of the kinetic rate equation are divided by \(\sqrt{K_H}\) in
order to reduce the number of variables since this allows lumping together \(K_H\) and \(K_{H2O}\).

Although the result is that the adsorption term is not dimensionless anymore, the result is
mathematically the same for the reaction rate expression. This expression is the sum of 6
terms with the exponent \(m=1\). The combined \(K_i\) factors for each term are specified in Table 4.

The adsorption constants are a function of temperature:
\[ K_i = a_i \exp(b_i/RT) \]  

Note that in Aspen Plus, \( K \) is expressed in a logarithmic form – for convenience, the resulting input parameters are also provided in Table 4.

\[ \ln(K) = A + \frac{B}{T} \]

Finally, the LHHW-kinetics was configured in Aspen Plus and tested with a plug flow reactor (PFR) against equilibrium and kinetics data from literature (An et al., 2009). An excess of catalyst was applied in order to reach the chemical equilibrium in the PFR. The comparison between the experimental and simulated data (illustrated in Table 5) shows a good agreement with less than 5% error around the operating process conditions, thus indicating a correctly implementation of the kinetics. No model parameters were calculated and no changes were made to the kinetic data from An et al. (2009) and the equilibrium data from Lim et al. (2009) – based on the detailed model of Graaf et al. (1986). These were only translated from the implicit form to the explicit input format required by the process simulator Aspen Plus.

4. Results and discussion

4.1.1 Sensitivity analysis

Within Aspen Plus, the CO₂ converter was simulated by a plug-flow reactor (PFR) using the Soave-Redlich-Kwong EOS and NRTL with Henry components as property models. The amount of catalyst considered in the reactor corresponds to a gas hourly space velocity of GHSV=5.9 m³/kgcat. Due to the geometrical design of the multi-tubular reactor, the gas velocity does not exceed 1.5 m/s. The following parameters were varied in the specified range: \( T=200-300°C, \ p=1-100 \ \text{bar}, \ \text{reactants ratio} \ \text{R=H}_2:\text{CO}_2=3-12, \ \text{and catalyst loadings within the range GHSV=0.1-10}^5 \ \text{m}^3/\text{kgcat.} \) The following figures show the main results of the sensitivity analysis, in terms of methanol and CO yield as a function of temperature (Figure 2 and Figure 3), pressure (Figure 4) and catalyst loading (Figure 5), at different reactants ratios. Due to the kinetic limitations at lower temperatures versus equilibrium limitations at higher temperatures, an optimal operating region exists and this depends on the reactants ratio. The effect of pressure on the MeOH and CO yields is straightforward. The formation of methanol is clearly favored at higher pressures due to the fact that CO₂ and CO hydrogenation reactions proceed with a decrease of the total number of moles. Consequently, as more CO is converted to methanol at higher pressures, the CO yield decreases when the pressure is increased. Figure 5 shows that at 200°C the reaction is kinetically limited, as an increase in catalyst loading leads to an increase in methanol yield. Therefore, it makes sense to increase the catalytic
activity at lower temperatures in order to improve the yield. However, at higher temperatures (>250°C) the reaction is equilibrium limited when a sufficient amount of catalyst is used (GHSV<10 m³/kgcat h), hence any further increase of the catalyst loading has no effect at all. Furthermore, Figure 6 shows the theoretical effect of water content in the reactor feed – more water leads to decreased performance as the presence of water has a detrimental effect on the equilibrium. However, it should be noted that in this new process the humidity (water content) of the hydrogen feed is not an actual variable, since the fresh feed stream is assumed to be saturated with water at ambient conditions hence this is the worst case scenario.

4.1.2 Process description

The classic low-pressure methanol process follows the generic scheme shown in Figure 7 (Fiedler et al., 2005) – which is a typical reaction-separation-recycle system (Kiss, 2010; Kiss et al., 2007). Basically, the reactants are brought to the required temperature and pressure then fed together (matching the stoichiometric number $\text{SN}=2$) to a reactor operated at 200-300°C and 50-100 bar. Due to the chemical equilibrium limitations, the conversion is incomplete so the reactor outlet will comprise of products (methanol and water) as well as unconverted reactants (COx and hydrogen). This gaseous mixture is cooled and flashed to separate the condensable products from the non-condensable reactants, which are recycled. The condensed components are then separated in two steps, typically by a direct distillation sequence, into lights (dissolved COx and minor light impurities), methanol and a water stream.

In this work, a plant capacity of 100 ktpy methanol is considered. Figure 8 presents the proposed process flowsheet, while the complete mass and energy balance is provided in Table 6. Compared to the classic low-pressure methanol process reported (Fiedler et al., 2005) there are several key differences, described hereafter. The fresh CO₂ feed stream is mixed with the recycle gas stream and fed to the feed-effluent-heat-exchanger (FEHE) without decompression and heating. This leads to a lower gas flowrate to the recycle compressor (COMP2) and thus reduced requirements of electricity.

Note that using classic process synthesis heuristics we have also evaluated alternative process configurations that aimed to take advantage of having separate hydrogen and CO₂ feed streams (e.g. higher flexibility and methanol yield, lower energy requirements). However, no significant improvement was observed by feeding the reactants as mixed or pure components all at once or added along the catalytic reactor. The main reason is that the reactor outlet is in all cases close to the equilibrium hence implicitly limited. Consequently, the strategy of feeding the reactants has no effect on a reactor reaching 100% of the equilibrium conversion.
The best alternative strategy was to feed the mixed reactants along the reactor working at lower end temperature, and to strip out the dissolved CO\textsubscript{2} from the methanol using the fresh feed of hydrogen that is then mixed with the CO\textsubscript{2} and the recycle stream. This strategy leads to the highest methanol yield and the lowest energy requirements per ton product. As shown later, this strategy is especially beneficial when wet fresh hydrogen is used, since the addition of wet fresh hydrogen does not only result in the stripping and recycling of CO\textsubscript{2} and CO from the produced methanol, but to removal of the water from the fresh hydrogen as well, thus leading to even bigger improvements in CO\textsubscript{2} conversion per pass and energy reduction.

The fresh wet hydrogen feed from chlorine production by salt electrolysis is pressurized to 45 bar in a primary multi-stage compressor (COMP\textsubscript{1}). The hydrogen compressor (COMP\textsubscript{1}) was optimized (e.g. reducing the intermediate cooling temperature to less than 170 °C) to take advantage of the compression curve, and therefore further reduce the compression duty. The resulting gas mixture is heated up in a feed-effluent heat-exchanger (FEHE) by the reactor outlet stream, and then fed to a multi-tubular plug-flow reactor (PFR) operated isothermally at 50 bar and 250°C. The heat of reaction generated in the reactor can be used to generate high pressure steam. The multi-tubular catalytic reactor has the following characteristics: 12 m length, 810 tubes of 0.06 m diameter, and a loading of 865 kg catalyst (Cu/Zn/Al/Zr). More catalyst could be added, but the improvements on the conversion are not significant since the operation under these conditions is practically equilibrium limited. A bed voidage (defined as the fraction of the reactor volume not occupied by catalyst) of 0.98 was used in simulations. This means that the fibrous Cu/Zn/Al/Zr catalyst reported in An et al. (2009) is taken on a support and that 0.02 volume fraction (based on reactor) of active catalyst material is used.

The reactor outlet stream is cooled down in the FEHE unit and an additional COOLER, then being eventually flashed in a separator (SEP) to split methanol and water (liquid) from the non-condensable gas components (CO, CO\textsubscript{2} and H\textsubscript{2}) that are recycled. The recycle stream is then purged (optionally, up to 1.5%) and mixed with the fresh CO\textsubscript{2} feed stream and sent to the second compressor (COMP\textsubscript{2}). The liquid stream of the flash is sent to a stripping column (STRIPPER) where the compressed wet hydrogen stream from COMP\textsubscript{1} is fed in counter-current mode. This has a double positive effect, as it dries the hydrogen feed thus removing water from the reactor feed, and it removes the light ends (mainly CO\textsubscript{2} but CO as well) which are completely recycled thus significantly improving the consumption figures. The liquid bottom stream of the stripper is sent to a distillation column (DC) that separates water as bottom product and methanol as high purity top distillate. It is worth noting that by using the stripper unit, the liquid outlet (containing methanol-water) is obtained at higher temperature – the
consequence of using a warmer feed stream to the DC unit being a reduced reboiler duty. Note
that the separation of the methanol-water stream is carried out in a single distillation column
using a partial condenser – able to deliver a vapor distillate (lights), high purity liquid
distillate (methanol) and bottom product (water). Consequently, one distillation column
(including reboiler and condenser) of the conventional direct sequence is spared. A dividing-
wall column can be also considered as an alternative for this ternary separation (Kiss, 2013),
in order to further reduce the (minor) methanol loss in the lights stream.

4.1.3 Consumption figures

For convenience, Table 7 gives the key parameters and consumption figures for this process.
Remarkable, a large part of the total reboiler duty (about 60%) can be covered by the thermal
energy produced in the reactor, by generating high pressure steam usable in the reboiler. It is
also worth noting that the consumption of raw materials is extremely close to the minimum
stoichiometric value, while the use of utilities (steam and electricity) is also very low. The
patent of Kiss et al. (2013) includes several comparative examples showing that at various
operating conditions this novel process using hydrogen stripping of products allows 15-20% energy savings and 5-8% more methanol product as compared to the conventional process.

For convenience, Table 8 shows a comparison between two cases not limited by equilibrium (without and with stripper) as described in the patent of Kiss et al. (2013) which provide more details about these cases and covers more possible process configurations. The advantages of using a stripping unit are clearly illustrated by the lower consumption figures, higher resource efficiency, as well as higher conversion of the raw materials.

5. Conclusions

The methanol synthesis by carbon dioxide hydrogenation is feasible in the new efficient process proposed here. A key feature of this novel process is the use of a stripping unit where
the wet hydrogen (saturated with water) flows in counter-current with the condensed mixture
methanol-water resulting from the flash separation after reaction. This operation has a double
positive effect, as it removes CO₂ from the methanol-water mixture thus allowing a complete
recycle of CO₂, while also removing the water from the wet hydrogen (initially saturated with
water) thus avoiding the negative impact on the reaction equilibrium conversion.

As a result, the consumption figures indicate a limited use of utilities (550 kWh/ton methanol,
and 0.48-1.16 ton steam per ton methanol) while the use of the raw materials is minimal, as
both reactants are recovered and recycled hence completely converted in the overall process –
being limited by the stoichiometry only. While all the carbon from the CO₂ feed ends up in
the methanol product, the hydrogen valorization is less efficient since only two thirds of
hydrogen is converted to methanol product, the rest being converted to the water by-product.

**Notation**

- $A$: pre-exponential factor
- $c$: concentration (mol/kg)
- $f$: fugacity (bar)
- $GHSV$: gas hourly space velocity (m³/kgₜₐₜ/h)
- $k$: reaction rate constant
- $K_R$: equilibrium constant of reaction $R$
- $K_i$: adsorption constant of component $i$ (1/bar)
- $m$: number of parameters (-)
- $p$: pressure (bar)
- $R$: gas constant = 8.314 (J/molK)
- $W$: weight of catalyst (kg)
- $y_i$: gas mol fraction of component $i$ (-)

**Greek symbols**

- $\Delta H$: enthalpy change (kJ/mol)
- $\Delta S$: entropy change (kJ/molK)
- $\theta_{CO}$: Langmuir adsorption term CO
- $\theta_{CO_2}$: Langmuir adsorption term CO₂
- $\theta_i$: fractional occupation of s1-sites with species $i$
- $\lambda_j$: fractional occupation of s2-sites with species $j$
- $\lambda_H$: Langmuir adsorption term for dissociated hydrogen

**Subscripts**

- $i$: component $i$ (e.g. CO, CO₂, H₂, CH₃OH, H₂O)

**Abbreviations**

- $SN$: Stoichiometric number
- $WGS$: Water-gas shift reaction
