Selective and Efficient Reduction of Carbon Dioxide to Carbon Monoxide on Oxide-Derived Nanostructured Silver Electro catalysts

Ming Ma, Bartek J. Trześniiewski, Jie Xie, and Wilson A. Smith*

Abstract: In this work, the selective electrocatalytic reduction of carbon dioxide to carbon monoxide on oxide-derived silver electro catalysts is presented. By a simple synthesis technique, the overall high faradaic efficiency for CO production on the oxide-derived Ag was shifted by more than 400 mV towards a lower overpotential compared to that of untreated Ag. Notably, the Ag resulting from Ag oxide is capable of electrochemically reducing CO₂ to CO with approximately 80% catalytic selectivity at a moderate overpotential of 0.49 V, which is much higher than that (ca. 4%) of untreated Ag under identical conditions. Electrokinetic studies show that the improved catalytic activity is ascribed to the enhanced stabilization of COOH intermediate. Furthermore, highly nanostructured Ag is likely able to create a high local pH near the catalyst surface, which may also facilitate the catalytic activity for the reduction of CO₂ with suppressed H₂ evolution.

The electrochemical conversion of CO₂ into carbon-based fuels is an attractive strategy for utilizing CO₂ captured at large emission sources. In order to close the anthropogenic carbon cycle, the electrocatalytic reduction of CO₂ to fuels should be powered by a renewable electricity source. For achieving this goal, the essential step is to develop a cheap, stable, and efficient catalyst with high selectivity for a desired product. Over the past few decades, several catalyst materials with the capability of reducing CO₂ electrochemically in CO₂ saturated-aqueous solutions have been identified. It has been demonstrated that polycrystalline Au is capable of reducing CO₂ to CO with a high faradaic efficiency (FE) of about 87% at −0.74 vs. reversible hydrogen electrode (RHE). While Au is currently the most efficient electrocatalytic surface for CO₂ reduction to CO, the low abundance and high cost of Au may prevent its large-scale applications. To find a cost-effective and stable catalyst with high selectivity and efficiency remains a challenge for achieving practical utilization of CO₂ reduction to CO.

Metallic Ag has attracted considerable attention due to its significantly lower cost compared to Au and high selectivity for the conversion of CO₂ to CO. However, the high overpotential (> 0.9 V) on Ag catalysts is required for driving the electrocatalytic reduction of CO₂ efficiently and selectively with suppressed H₂O reduction. The large overpotential required for the reduction of CO₂ is attributed to the hindrance for the initial electron transfer to a CO₂ molecule. Lu et al. reported that a nanoporous Ag catalyst with a fast initial electron transfer prepared by the de-alloying of an Ag-Al precursor is capable of reducing CO₂ electrochemically to CO efficiently and selectively at reduced overpotential. Recently, Kanan et al. discovered that oxide-derived Cu and Au nanoparticle films exhibit a dramatically improved selectivity for the reduction of CO₂ to CO at low overpotential and high resistance to catalytic deactivation compared to polycrystalline metals.

This study is the first exploration of the catalytic activity of the electrochemical reduction of CO₂ on oxide-derived nanostructured Ag catalysts (OD-Ag). Here we demonstrate that a nanostructured Ag electrode resulting from silver oxide is capable of electrochemically reducing CO₂ to CO with high selectivity at much lower overpotential compared to that of the polycrystalline Ag, and the increased catalytic activity is linked to the improved stabilization of the COOH intermediate.

The thermal oxidation of Ag foils is prohibited because the decomposition of silver oxide becomes significant at temperatures above 200°C. Here, we used a simple and scalable electrochemical method for oxidizing Ag electrodes. Potential anodization in alkaline solutions was an effective and simple method for the formation of Ag oxide on Ag electrodes. Here, an electrode made of a polycrystalline Ag foil was immersed in 0.2 M NaOH solutions in a two-compartment cell with a Pt counter electrode and an Ag/AgCl reference electrode (cyclic voltammetry of Ag in 0.2 M NaOH is shown in Figure S1 in the Supporting Information). The two-compartment cell was separated by a Nafion-115 proton exchange membrane to avoid Pt deposition on Ag electrodes during the electrochemical synthesis. A symmetric 50 Hz square-wave pulsed potential was applied on Ag electrodes to synthesize Ag oxide layers. We found that the fabricated Ag oxide layers exhibit a porous structure, as shown in Figure S2. The resulting Ag oxide electrodes were directly used in the electrochemical reduction of CO₂, and were electrochemically reduced to metallic Ag in the early stage of electrolysis.

Figure 1a,b show scanning electron microscope (SEM) images of electrodes resulting from Ag oxide after the
electrocatalytic reduction of CO₂ in CO₂-saturated electrolytes. The SEM images indicate that a porous-like nanostructured Ag surface was formed as a result of the reduction of Ag oxide after electrolysis. The X-ray diffraction (XRD) pattern in Figure 1c confirms the presence of Ag₂O on Ag foil synthesized by anodization in alkaline solutions. After CO₂ reduction electrolysis, XRD pattern shows only Ag peaks with no more indication of any remaining Ag oxide. In addition, the Ag foil fabricated by anodization turned a black color (Figure S3), which is also indicative of the formation of Ag oxide, and the sample had no remaining black color after CO₂ reduction electrolysis.

To further confirm the composition of the samples before and after electrolysis, X-ray photoelectron spectroscopy (XPS) measurements were performed. The Ag 3d₅/₂ peak at 368.2 eV was observed for polycrystalline Ag in Figure 1d, which is also indicative of the formation of Ag oxide, and the sample had no remaining black color after CO₂ reduction electrolysis.

The electrocatalytic reduction of CO₂ on OD-Ag and polycrystalline Ag were performed in CO₂-saturated 0.1 M KHCO₃ (99.95 %) electrolyte (pH 6.83) at ambient temperature and pressure. In the initial period of electrolysis, OD-Ag electrodes were directly formed in situ by the electroreduction of the Ag oxide film formed on the Ag electrode. CO₂ reduction electrolysis experiments were performed in an electrochemical cell consisting of working and counter electrode compartments, separated by a Nafton-115 proton exchange membrane to prevent the oxidation of CO₂ reduction products. The cathodic compartment was continuously purged with CO₂ at a constant flow rate and vented directly into the gas-sampling loop of a gas chromatograph (GC) for the periodic quantification of the gas-phase products. Liquid products formed in the CO₂ reduction were detected by ¹H nuclear magnetic resonance (NMR) spectroscopy after completion of the electrolysis experiments.

The comparison of the CO₂ reduction activity of untreated polycrystalline Ag and OD-Ag is presented in Figure 2. The OD-Ag exhibited a high initial current density (j₁) (Figure S4), which stems from the reduction of the Ag oxide layer in the initial period of electrolysis. Subsequently, the OD-Ag exhibited a j₁ of 1.15 mA cm⁻² with CO faradaic efficiency of 89 % at −0.8 V vs. RHE, as shown in Figure 2a. At a less negative potential of −0.7 V vs. RHE, a decreased FE of 82.4 % for CO formation was observed (Figure 2b). Notably, the FE of 80 % for CO production was achieved at −0.6 V vs. RHE (Figure 2c), which corresponded to a modest overpotential (h₁) of 0.49 V relative to the CO₂/CO equilibrium potential of −0.11 V vs. RHE. In contrast, the polycrystalline Ag electrodes experienced low j₁, accompanying by very low FE for CO formation (22.4 %, 12 % and 4.1 % at −0.8 V, −0.7 V and −0.6 V vs. RHE, respectively).

To better understand the catalytic activity for CO₂ reduction, the FE for the major products of CO₂ reduction was plotted at various potentials for the polycrystalline Ag and the OD-Ag (Figure 3). As noted in Figure 3a, the FE for
the electrochemical reduction of CO$_2$ to CO on both the polycrystalline Ag and the OD-Ag gradually increased with enhancing overpotentials. The increase of the FE for CO corresponds to a decrease in the related FE for H$_2$ production (Figure 3b). In addition, a small amount of formate was only detected at high overpotentials (Figure S5). Interestingly, Figure 3a shows that the overall FE for CO on the OD-Ag was shifted by $>400$ mV toward the positive potential compared to that of untreated Ag (at a FE range for CO of more than 30%). In addition, the current density for CO production as a function of potentials in Figure 3c implies the onset potential for CO$_2$ reduction on OD-Ag was $-0.4$ V vs. RHE (f$\text{CO}_2 = 0.29$ V), which is a positive shift by about 200 mV compared to that ($-0.6$ V vs. RHE) of polycrystalline Ag. More importantly, for driving the electrocatalytic reduction of CO$_2$ to CO with a FE of 80%, a potential of $-0.6$ V vs. RHE was required on OD-Ag, which is significantly reduced by 500 mV compared to that of untreated Ag ($-1.1$ V vs. RHE). These results indicate that OD-Ag acts as an efficient catalyst for the electrocatalytic reduction of CO$_2$ to CO with significantly suppressed H$_2$ evolution at decreased overpotentials.

To gain insight into the electrokinetic mechanism of CO$_2$ reduction on both catalysts, Tafel analysis was performed. Here, Tafel plots of the OD-Ag and the polycrystalline Ag (overpotential versus log of the partial current density for CO production) are shown in Figure 4. Hori has proposed that a two-electron transfer is involved in the electrochemical reduction of CO$_2$ to CO (Scheme 1). In addition, most of the computational studies on reaction paths for CO$_2$ reduction are based on the computational hydrogen electrode (CHE) model, in which it is assumed that a proton-coupled electron transfer (PCET) takes place at every reaction step. Thus, a COOH intermediate is formed by a PCET as the first CO$_2$ activation step in density functional theory (DFT) simulations. However, in some experimental work, it is believed that the adsorbed CO$_2$ intermediate is formed on the active sites of the metal surface through a one-electron transfer to a CO$_2$ molecule, and then the COOH intermediate is produced after accepting one proton. Furthermore, it was reported that the first donation of a proton is from HCO$_3^-$.

A Tafel slope of 133 mV dec$^{-1}$ for polycrystalline Ag shown in Figure 4a corresponds to a transfer coefficient of 0.44 [Eq. (S2)]. This slope and the transfer coefficient are consistent with the fact that the rate-determining step is the initial electron transfer to CO$_2$. In contrast, OD-Ag exhibited a low Tafel slope of 77 mV dec$^{-1}$ at low overpotentials, which indicates a fast initial electron transfer to a CO$_2$ molecule according to previous studies. Subsequently, we found a dramatic increases of the Tafel slope for OD-Ag at relatively high overpotentials, indicating the CO$_2$ electroreduction may reach a mass transport limitation on the porous-like nanostructured Ag. Thus, while the mass transport in a nanostructured Ag catalyst is likely slower than in an untreated Ag (flat surface) at relatively high

It was reported that the surface of nanostructured Ag catalysts can provide the low-coordinated surface Ag sites, which plays a significant role for stabilizing the COOH intermediate through reducing the activation energy barrier of the initial electron transfer.[139] In addition, Kanan et al. proposed a grain boundary effect for OD-Cu[37] and OD-Au.[36] Here we propose a local pH effect to offer a new insight into the correlation of nanostructured Ag catalysts with the catalytic activity for CO2 reduction. The pH rises locally at the electrode/electrolyte interface because of releasing OH− in the cathodic reactions (Equation S (4-5)).[19] Thus, the pH close to the electrode (local pH) is higher than the bulk pH. To understand the local pH effect, CO2 reduction was performed on flat Ag and OD-Ag in 0.1m K2HPO4 and 0.1m KHCO3, respectively. The FE for CO on flat Ag was significantly reduced (Figure 5a) with dramatically enhanced FE for H2 (Figure 5c) in CO2-saturated 0.1m K2HPO4, which is consistent with the work of Hori on flat Cu (FE for H2 is 72.4% and 10.9% in 0.1m K2HPO4 and 0.1m KHCO3, respectively).[19] This observation is due to the fact that the buffer action of CO2-saturated 0.1m K2HPO4 can easily neutralize OH− generated at the electrode surface, keeping local pH at relatively low value. The low pH value at the electrode/electrolyte interface favors H2 evolution.[11] To further improve the local pH effect, CO2 reduction was also measured on flat Ag in 0.1m KClO3. KClO3 does not have buffer ability, which results in a relatively high local pH at the electrode/electrolyte interface. We found that the FE for CO in CO2-saturated 0.1m KClO3 was obviously higher than that of CO2-saturated 0.1m KHCO3 (Figure 5a). These observations (the FE for CO on flat Ag: KClO3 > KHCO3 > K2HPO4) imply that the local pH may play an important role in the reduction of CO2.

In contrast, we found that FE for CO on OD-Ag was almost equal in the two different electrolytes (Figure 5b) at various potentials. This observation may be partly attributed to that the limitation of the diffusion process in nanoporous Ag catalysts (Figure 1a,b) hinders the neutralization reaction for OH− generated near the catalyst surface, resulting in a high local pH in 0.1m K2HPO4. In addition, H2 evolution is not favorable at the high pH value. Thus, the high local pH created in nanoporous Ag may contribute to the suppressed H2 evolution (Figure 5d) with preferred CO2 reduction (Figure 5b).

In summary, nanostructured Ag catalysts prepared by electrochemically reducing Ag2O exhibited an enhanced catalytic activity for the reduction of CO2, and the high selectivity for CO was shifted by more than 400 mV to a lower overpotential than that of untreated polycrystalline Ag. At a moderate overpotential of 0.49 V, the oxide-derived nanostructured Ag was able to reduce CO2 to CO with about 80% faradaic efficiency, which is dramatically higher compared to that (ca. 4%) of untreated polycrystalline Ag at identical conditions. The dramatically improved catalytic activity and selectivity for CO2 reduction to CO is likely correlated with the nanostructured surface, resulting in highly active sites for stabilizing COOH intermediate. In addition, a high local pH generated within the porous-like nanostructured Ag catalysts may also play a role in the improved CO2 reduction along with suppressed H2 evolution. This study shows that a selective and cost-effective oxide-derived Ag catalyst can efficiently and selectively reduce CO2 to CO. While the catalytic activity of this oxide-derived Ag catalyst is not as high as the recent oxide-derived Au, its cost is significantly lower, and thus this catalyst and synthetic approach may provide a more practical platform for large-scale CO2 electroreduction.
