Abstract—In order to identify a specific system (module) of interest embedded in a dynamic network, one typically has to formulate a multi-input single-output (MISO) identification problem which requires to identify all modules in the MISO structure, and determine their model order. While the former task poses the problem of estimating a large number of parameters that are of no interest to the experimenter, the latter task may result computationally challenging in large-size networks. To avoid these issues and increase the accuracy of the identified module of interest, we use regularized kernel-based methods. Keeping a parametric model for the module of interest, we model the impulse response of the remaining modules in the MISO structure as zero mean Gaussian vectors with covariance matrix (kernel) given by the first-order stable spline kernel, accounting also for the noise model affecting the output of the target model. Using an Empirical Bayes (EB) approach, the target-module parameters are estimated by maximizing the marginal likelihood of the module output. The related optimization problem is solved using the Expectation-Maximization (EM) algorithm. Numerical experiments illustrate the potentials of the introduced method in comparison with the state-of-the-art techniques for local identification.

I. INTRODUCTION

In recent years increasing attention has been devoted by the system identification community to the identification of dynamic networks. Within a large body of literature in this topic, we can distinguish three main research trends. The first one concerns detection of the network topology [16], [5], [12]. The second research trend focuses on the identification of the full network dynamics [11], [24], [23], [25], while the third studies the identification of a specific component (usually referred to as a module) of the network; under the assumption of known topology, the identification of a target module in a dynamic network is discussed in [21], [7], [13]. In these contributions, classic methods for closed-loop identification such as the direct method [14] and the two-stage method [22], are generalized to a dynamic network framework. The setting of the aforementioned contributions is generalized in [6], where also sensor noise affecting the measurements is considered. In [10], a method known as simultaneous minimization of the prediction error is introduced to identify a specific module in a dynamic network with only sensor noise. The method is extended to a Bayesian setting in [9], where regularized kernel-based methods are used to reduce the mean-square error of the identified target module.

Using a reasoning similar to [9], in this paper we aim at improving the performance of the direct method for dynamic networks introduced in [21]. In that work it was shown that, in order to identify a given module of interest, we have to formulate a multi-input single-output (MISO) identification problem where the modules constituting the MISO structure correspond to the modules of the network sharing the same output with the module of interest (see Sec. III-A for details). This implies that, to avoid possible bias in the parameter estimates, one has to identify all the modules constituting the MISO structure, bringing in the problem a possibly very high number of parameters to be estimated that are of no interest to the experimenter. In addition to it, it may be required to select the number of parameters of each of these additional modules using complexity criteria such as AIC, BIC, or cross validation [14]. If the number of modules is high, one may have to test a huge combination of candidate model orders, making model order selection a computationally infeasible step (e.g., for 5 modules with FIR model structure and orders from 1 to 5, one has to test $5^5$ possible combinations).

To avoid model order selection issues and reduce the number of nuisance parameters in local module identification, we introduce a novel identification method based on regularized nonparametric kernel-based methods (see [19] for a survey on this subject). Considering known topology, we keep a parametric model for the module of interest in order to have an accurate description of its dynamics. As for the remaining modules of the MISO structure, we model their impulse responses as zero mean Gaussian processes. The covariance matrix (usually called a kernel) is given by the first-order stable spline kernel [4], [19], which encodes stability and smoothness of the processes. We also incorporate the process noise model indirectly through the impulse response modeling. The setup is different from [5], where all the modules are modeled as Gaussian processes.

Using this approach, we obtain a Gaussian probabilistic description that depends on a vector of parameters $\eta$ containing the parameters of the module of interest, the variance of the noise, and the hyperparameters characterizing the stable spline kernel. Therefore, by estimating $\eta$ we can obtain the parameters of interest. To accomplish this task, we use an Empirical Bayes (EB) approach [15], where $\eta$ is estimated by maximizing the marginal likelihood of the data. The solution of the problem is obtained by using an iterative scheme based on the Expectation-Maximization (EM) method [8], which turns out computationally attractive. Numerical experiments

on a simple dynamic network show the potentials of the developed method in comparison with the direct method and the two-stage method.

II. Problem Statement

Following the setting of [21], we consider a dynamic network that is built up of \( L \) measurable internal variables or nodes \( w_j(t), j = 1, \ldots, L \). The dynamic network can be defined by the equation (time and frequency dependence is omitted below),

\[
\begin{bmatrix}
  w_1 \\
  w_2 \\
  \vdots \\
  w_L
\end{bmatrix}
= G^0(q) w(t) + r(t) + v(t),
\]

In this equation,

- \( q^{-1} \) is the delay operator i.e. \( q^{-1} u(t) = u(t-1) \); 
- \( G^0_j(q) \) is a strictly proper rational transfer function for \( j = 1, L \) and \( i = 1, \ldots, L \); 
- \( v_j(t) \) is unmeasured process noise entering node \( w_j(t) \).

It is a realization of a stationary stochastic process represented by \( v_j(t) = H^0_j(q) \varepsilon_j(t) \), with \( \varepsilon_j(t) \) a Gaussian white noise process with unknown variance \( \sigma^2_j \) and \( H^0_j(q) \) a monic, stable and minimum phase filter; 
- \( r_j(t) \) is a measured external reference signal entering node \( w_j(t) \). In some nodes, it may be absent.

The following assumptions are made on the considered dynamic network.

**Assumption 1:** The dynamic network is stable, i.e. \((I - G^0(q))^{-1}\) is stable, and well posed (see [21] for details).

**Assumption 2:** The process noise \( v_j(t) \) entering the node \( w_j(t) \) is uncorrelated with the process noise entering any other node of the network.

We assume that we have collected \( N \) measurements of the internal variables \( \{w_k(t)\}_{i=1}^{N}, k = 1, \ldots, L \), and that we are interested in building a model of the module directly linking node \( i \) to node \( j \), that is \( G^0_{ij}(q) \), using these measurements. To this end, we choose a parameterization of \( G^0_{ij}(q) \), denoted as \( G_{ij}(q, \theta) \), that describes the dynamics of the module of interest for a certain parameter vector \( \theta_0 \in \mathbb{R}^n \).

III. The Developed Identification Technique

In this section we describe the developed method for identification of module \( G^0_{ij}(q) \).

A. The standard direct method

Following the above definition of a dynamic network, the node signal \( w_j(t) \) follows the equation

\[
w_j(t) = \sum_{k \in \mathcal{N}_j} G^0_{jk}(q) w_k(t) + r_j(t) + v_j(t),
\]

where \( \mathcal{N}_j \) is the set of indices of internal variables \( w_k(t) \) (\( k \neq j \) and \( G^0_{jk}(q) \neq 0 \)) that have direct causal connections with \( w_j(t) \). The above equation represents a MISO structure and is the starting point of the methodology presented in this paper, which is based on extending the direct method [21]. We construct the one-step ahead predictor [14] of \( w_j(t) \):

\[
w_j(t|t-1; \theta) = (1 - (H^0_j)^{-1}(q)) w_j(t) + (H^0_j)^{-1}(q) G_{ij}(q, \theta) w_i(t) + (H^0_j)^{-1}(q) \sum_{k \in \mathcal{N}_j \setminus \{i\}} G^0_{jk}(q) w_k(t) + r_j(t),
\]

which is a function of the parameter vector \( \theta \) entering the target module \( G^0_{ij}(q) \). In the standard direct method for dynamic networks [21], all the modules \( G^0_{jk}(q), k \in \mathcal{N}_j \), and the noise model \( H^0_j(q) \), are suitably parameterized with additional parameters. The parameter vector of interest \( \theta \) is identified by minimizing the prediction error \( \varepsilon_j(t) = w_j(t) - \hat{w}_j(t|t-1; \theta) \). We note that in this formulation, the prediction error depends also on the additional parameters entering the remaining modules and the noise model, which need to be identified to guarantee consistent estimates of \( \theta \). Therefore, the total number of parameters may grow large if the cardinality of \( \mathcal{N}_j \) is large, with a detrimental effect on the variance of the estimate of \( \theta \) in the case where \( N \) is not very large.

B. The direct method meets the Empirical Bayes approach

We now discuss how to use regularized kernel-based methods to avoid parameterization of the additional modules in the MISO structure. We define the following quantities:

\[
S^0_j(q) := 1 - (H^0_j)^{-1}(q), \quad S^0_{jk}(q) := (H^0_j)^{-1} G_{jk}(q),
\]

where \( k \in \{\mathcal{N}_j\} \setminus i \). Considering the parameterization of \( G^0_{ij}(q) \), Eq. (2) can be re-written as

\[
w_j(t) = S^0_j(q) w_j(t) + (1 - S^0_j(q)) G_{ij}(q, \theta) w_i(t) + r_j(t) + \sum_{k \in \mathcal{N}_j \setminus \{i\}} S^0_{jk}(q) w_k(t) + e_j(t).
\]

Next, we consider a time-domain description of the module dynamics. Our goal is to obtain a vector description of the network dynamics for the available \( N \) measurements. Since \( H^0_j(q) \) is monic, proper and has a stable inverse, then \( (H^0_j)^{-1}(q) \) is also monic, proper and stable. The impulse response of \( (H^0_j)^{-1}(q) \) is represented as

\[
(H^0_j)^{-1}(q) = \tilde{h}_j(0) + \sum_{d=1}^{\infty} \tilde{h}_j(d) q^{-d},
\]

where \( \tilde{h}_j(0) = 0 \). Similarly, the impulse response of \( S^0_j(q) \) is represented as \( S^0_j(q) = \sum_{d=1}^{\infty} s_j(d) q^{-d} \), and the impulse response of the target module is written as \( G_{ij}(q, \theta) = \sum_{d=1}^{\infty} g_{ij}(d, \theta) q^{-d} \). For notation purposes, we consider the first \( N \) samples of \( g_{ij}(d, \theta) \) and collect them in the \( N \)-dimensional vector \( g_{ij} \) (which will also depend on \( \theta \), although we will keep this dependence tacit). Similarly, we define the vector \( s_k, k \in \{\mathcal{N}_j\} \setminus i \), and \( s_j \) as the vectors containing the first \( l \) coefficients of the impulse responses of \( S^0_{jk}(q), k \in \{\mathcal{N}_j\} \setminus i \), and \( S^0_{ij}(q) \), respectively. The integer \( l \) is chosen large enough to ensure \( s_k(l+1) \) and \( s_j(l+1) \) are not zero.

Next, we introduce a vector notation for the node \( w_j(t) \):

\[
w_j := [w_j(1) \ldots w_j(N)]^T.
\]
and we denote by \( W_k \in \mathbb{R}^{N \times l} \) the Toeplitz matrix of the vector \( w_k := [0 \ w_k(1) \ldots \ w_k(N-1)]^T, \ k \in \{N_j \cup j\} \setminus \{i\} \) and \( \tilde{W}_i \in \mathbb{R}^{N \times N} \) the Toeplitz matrix of the vector \( \tilde{w}_i := [0 \ \tilde{w}_i(1) \ldots \ \tilde{w}_i(N-1)]^T \). Similarly, we denote by \( \tilde{W}_i \in \mathbb{R}^{N \times l} \) the Toeplitz matrix of the vector \( \tilde{w}_i := [0 \ \tilde{w}_i(1) \ldots - \tilde{w}_i(N-2)]^T \), and by \( G_0 \) the Toeplitz of \( g_j \). Without loss of generality, we can assume \( r_j(t) = 0 \) for the sake of brevity. With the above notations in place, we can rewrite the network dynamics in the following vector form:

\[
\mathbf{w}_j = \tilde{W} s_j + \mathbf{W}_i \mathbf{g}_{ji} + \sum_{k \in \mathcal{N} \setminus \{i\}} W_k s_k + e_j,
\]

where \( \tilde{W} := \tilde{W}_j + G_0 \tilde{W}_i \) and \( e_j \) is the vectorized noise.

Having set a convenient notation for the network dynamics, we now discuss in details our modeling strategy. Our goal is to limit the number of parameters necessary to describe \( w_j \) in (6), in order to increase the accuracy of the estimated parameter vector of interest \( \theta \). Therefore, while we keep a parametric model for \( g_j \), for the remaining impulse responses in (6) we use nonparametric models induced by Gaussian processes [20]. The choice of Gaussian processes is motivated by the fact that it enforces enjoyable structure of this kernel is given by

\[
\text{First-order Stable Spline kernel.}
\]

The covariance matrix of these vectors, usually referred to as a kernel in this context, is chosen to be corresponding to Gaussian processes \([20]\). The choice of Gaussian processes in (6) we use nonparametric models induced by

\[
\text{Gaussian processes \([20]\).}
\]

We use an iterative solution scheme through the EM algorithm. To do so, we first have to define a latent variable whose estimation simplifies the computation of the marginal likelihood. In our case, a natural choice is \( \eta \). Then, the EM algorithm iterates among the following two steps:

- **E-Step:** Given an estimate \( \hat{\eta}^{(n)} \) computed at the \( n \)th iteration, compute

\[
Q^{(n)}(\eta) = \mathbb{E}[\log p(w_j, s; \eta)] ,
\]

which is the expected value of the joint log-likelihood of \( w_j \) and \( s \) with respect to the posterior \( p(s|w_j; \hat{\eta}^{(n)}) \);

- **M-Step:** Update \( \hat{\eta} \) by solving

\[
\hat{\eta}^{(n+1)} = \arg \max_{\eta} Q^{(n)}(\eta) .
\]
Iterating among the above steps, convergence to a stationary point of the marginal likelihood is ensured [3]. Clearly, we get an advantage from using the EM algorithm if repetitively solving (19) is significantly easier than solving the original marginal likelihood problem (17). In the following subsections, we show that this is indeed the case.

A. Computation of E-step

First we focus on the E-step. The posterior distribution of $s$ given $w_j$ and an estimate of $\eta$ is Gaussian and corresponds to (see also [1]),

$$p(s|w_j;\eta) \sim \mathcal{N}(C(w_j - W_i g_{ji}), P_s),$$

(20)

where

$$P_s = \left( \frac{W^TW + K^{-1}}{\sigma_j^2} \right)^{-1} = \frac{C}{\sigma_j^2}.$$

Let $\hat{s}^{(n)}_j$ and $\hat{P}_s^{(n)}$ be the posterior mean and covariance of $s$ obtained from (20) using $\hat{\eta}^{(n)}$. We define $\hat{S}^{(n)} := \hat{P}_s^{(n)} + \hat{s}^{(n)} \hat{s}^{(n)\top}$, and consider its $l \times l$ diagonal blocks, which we denote by $\hat{S}^{(n)}_i, \hat{S}^{(n)}_k, \ldots, \hat{S}^{(n)}_{K_p}$. Respectively, these submatrices correspond to the posterior second moments of the estimated impulse responses $\hat{s}^{(n)}_j, \hat{s}^{(n)}_k, \ldots, \hat{s}^{(n)}_{K_p}$.

The following lemma provides the structure of the function $Q^{(n)}(\eta)$ for the particular situation of our setup in (17).

**Lemma 1:** Let $\hat{\eta}^{(n)}$ be the estimate of $\eta$ at $n^{th}$ iteration of the EM algorithm. Then

$$Q^{(n)}(\eta) = Q_0^{(n)}(\sigma_j^2, \theta) + \sum_{k \in \{N_j \cup j\} \setminus \{i\}} Q_{k}^{(n)}(\lambda_k, \beta_k),$$

(21)

where

$$Q_0^{(n)}(\sigma_j^2, \theta) = -N \log(\sigma_j^2) - \frac{1}{\sigma_j^2} \left[ w_j^TW_j - 2w_j^TW_i g_{ji} + g_{ji}^TW_i^TW_j g_{ji} - 2w_j^TW_i^T \hat{W} \hat{S}^{(n)} + 2g_{ji}^TW_i^T \hat{W} \hat{S}^{(n)} + \text{tr}(W_i^T W_i \hat{W} \hat{S}^{(n)}) \right].$$

(22)

$$Q_k^{(n)}(\lambda_k, \beta_k) = - \log \det(\lambda_k K_{\beta_k}) - \text{tr}((\lambda_k K_{\beta_k})^{-1} \hat{S}_k^{(n)}).$$

(23)

It is seen that the function $Q^{(n)}(\eta)$ is the summation of several terms that depend on different components of the vector $\eta$. In particular, we have a term of the type $Q_{k}^{(n)}(\lambda_k, \beta_k)$ for each module in the MISO structure, and a term $Q_0^{(n)}(\sigma_j^2, \theta)$ for the module of interest and the noise variance. Therefore, the update of $\eta$ splits into a number of independent and smaller optimization problems.

B. Computation of M-step

We now focus on the M-step. From (21), it is evident that each kernel hyperparameter can be updated independently of the rest of the parameters. The following theorem, inspired from [2] and [9], shows how to update the kernel hyperparameters.

**Theorem 1:** Define

$$Q_{\beta_k}^{(n)}(\beta_k) = \log \det(K_{\beta_k}) + l \log \left( \text{tr}(K_{\beta_k}^{-1} \hat{S}_k^{(n)}) \right)$$

(24)

for $k \in \{N_j \cup j\} \setminus \{i\}$. Then,

$$\hat{\beta}_k^{(n+1)} = \arg \min_{\beta_k \in \mathbb{R}^l} Q_{\beta_k}^{(n)}(\beta_k);$$

(25)

$$\lambda_k^{(n+1)} = \frac{1}{l} \text{tr}((K_{\beta_k}^{(n+1)})^{-1} \hat{S}_k^{(n)}).$$

(26)

We note that from (26) we get closed form solutions for all $\lambda_k, k \in \{N_j \cup j\} \setminus \{i\}$, while the $\beta_k, k \in \{N_j \cup j\} \setminus \{i\}$, can be updated by solving scalar optimization problems in domain $[0,1]$, as detailed in (25). Therefore, the hyperparameters update turns out to be a computationally fast operation.

We now turn our attention to $\theta$ and $\sigma_j^2$. We notice that the optimum with respect to $\theta$ does not depend on the optimal value of $\sigma_j^2$. Then, we can first update $\theta$ and then use its optimal value to update $\sigma_j^2$. How to update of $\theta$ is explained in the following theorem.

**Theorem 2:** The parameter vector $\theta$ is updated by solving the nonlinear least-squares problem

$$\hat{\theta}^{(n+1)} = \arg \min_{\theta} \left[ g_{ji}^T A(n) g_{ji} - 2\hat{b}^{(n)}_i^T g_{ji} \right],$$

(27)

where $A(n)$ and $\hat{b}^{(n)}_i$ are computed using the current estimates $\hat{s}^{(n)}_j$ and $\hat{\eta}^{(n)}$. The expression of $A(n)$ and $\hat{b}^{(n)}_i$ is given in the appendix. Therefore, the parameter vector of the target module is updated by solving a (generally) nonlinear least-squares problem given by (27). If $g_{ji}$ is linearly parameterized with $\theta$ (e.g. in case of FIR models), the above problem becomes quadratic and a closed-form solution is achieved. That is, if $g_{ji} = M \theta$ where $M \in \mathbb{R}^{N \times n_a}$, then

$$\hat{\theta}^{(n+1)} = (M^T A(n) M)^{-1} M^T \hat{b}^{(n)}.$$

(28)

We are left with updating $\sigma_j^2$. This is done in the following statement.

**Theorem 3:** Let $\hat{g}^{(n+1)}_j, \hat{W}^{(n+1)}$ be constructed by inserting $\hat{\theta}^{(n+1)}$ in the general expression of $g_{ji}$ and $W$. Then

$$(\sigma_j^2)^{(n+1)} = \frac{1}{N} \left[ \|w_j - W_i \hat{g}^{(n+1)}_{ji}\|_2^2 - 2w_j^T W_i^T \hat{W}^{(n+1)} \hat{s}^{(n)} + 2g_{ji}^T W_i^T \hat{W}^{(n+1)} \hat{s}^{(n)} + \text{tr}(\hat{W}^{(n+1)\top} \hat{W}^{(n+1)} \hat{S}^{(n)}) \right].$$

Thus, a closed form solution for the noise variance is also obtained.

All-in-all, we have obtained a fast iterative procedure that provides a local solution to the marginal likelihood problem (17). Except for $\theta$ that requires solving a nonlinear optimization problem at each iteration, all the updates follow simple rules that allow for fast iterative computation. Algorithm 1 summarizes the steps to follow to obtain $\hat{\eta}$ and therefore $\hat{\theta}$. The initialization can be done by randomly choosing $\eta$. 

Considering the constraints of hyperparameters, the convergence criterion for the algorithm depend on the value of considering the constraints of hyperparameters. The convergence criterion for the algorithm depend on the value of \( \| \hat{\theta}^{(n)} - \hat{\theta}^{(n-1)} \| \). This value should be small for convergence so that the algorithm can be terminated. A value of 10^{-9} is considered for the numerical experiment in Sec. V.

V. NUMERICAL EXPERIMENTS

Numerical experiments are performed to evaluate the performance of the developed method, which we abbreviate as Empirical Bayes Direct Method (EBDM). To this end, the EBDM is compared with the standard direct method and the two-stage method (see [21] for details). The comparison is made on the dynamic network depicted in Fig. 1. The goal is to identify \( G_{31}(q) \). The network modules are given by

\[
G_{31}^0 = q^{-1} + 0.05q^{-2} + \frac{b_0^0 q^{-1} + b_2^0 q^{-2}}{1 + a_0^0 q^{-1} + a_2^0 q^{-2}};
\]

\[
G_{32}^0 = -0.36q^{-1} - 0.063q^{-2} + 0.02q^{-3} + 0.005q^{-4};
\]

\[
G_{34}^0 = 1 - 0.859q^{-1} - 1.04q^{-2} + 0.052q^{-3} + 0.011q^{-4};
\]

\[
G_{34}^0 = 1.18q^{-1} + 0.647q^{-2} + 0.151q^{-3} - 0.082q^{-4};
\]

\[
G_{14}^0 = \frac{0.4q^{-1} - 0.5q^{-2}}{1 + 0.3q^{-1}}; H_1^0 = \frac{1}{1 + 0.2q^{-1}};
\]

\[
G_{12}^0 = \frac{0.4q^{-1} + 0.5q^{-2}}{1 + 0.3q^{-1}}; H_2^0 = \frac{1}{1 + 0.3q^{-1}};
\]

\[
H_4^0 = 1 - 0.505q^{-1} + 0.155q^{-2} - 0.01q^{-3}; H_4^0 = 1.
\]

We run 50 independent Monte Carlo experiments where the data is generated using known reference signals \( r_2(t) \) and \( r_4(t) \) that are realizations of white noise with unit variance. The number of data samples is \( N = 500 \). The noise sources \( e_1(t) \), \( e_2(t) \), \( e_3(t) \) and \( e_4(t) \) have variance 0.05, 0.08, 1, 0.1, respectively. We assume that we know the model order of \( G_{31}^0(q) \). In the case of direct method, we solve a 3-input/1-output MISO identification problem with \( w_1(t) \), \( w_2(t) \) and \( w_3(t) \) as inputs. In the two-stage method, the projection of the three inputs on external signals \( r_1(t) \) and \( r_2(t) \) are used as inputs to the MISO identification problem. For both these methods, we consider the case where the model order selection of all the modules in the MISO structure (except for the target module) is required, and the case where the model orders are known. Moreover, in order to improve the accuracy of the identified module in the two-stage method, we identify the noise model even though it is not necessary.

The box plots of the fits of the impulse response of \( G_{31}(q) \) are shown in Fig. 2, where we have compared the two-stage method with true model orders (‘TS+TO’), the direct method with true model orders and model orders selected via BIC (‘DM+TO’ and ‘DM+MOS’, respectively), and the Empirical Bayes Direct Method (‘EBDM’). As for the latter, we choose \( l = 100 \). It can be noted that in this setup the EBDM achieves better fit than the classic methods. Fig. 3 shows the mean and standard deviation of the parameter estimates obtained by the Two-stage method, Direct method and proposed method. Number of data samples used for estimation is \( N = 500 \).
of $G_{ij}$. It is evident that the EBDM gives a smaller bias and a greatly reduced variance compared to the other considered identification methods. The reduction in variance is attributed to the regularization approach used in this method. Considering a relatively small sized network with 3 modules in the MISO structure, the developed method proves effective. When the size of the network grows, the results of the direct order selection step contributes to inaccurate results. Thus further, it is expected that in large networks the model method may deteriorate further due to increase in variance; when the size of the network grows, the results of the direct method for the MISO structure, the developed method proves effective.

VI. CONCLUSIONS

An effective regularized kernel-based approach for local module identification in large dynamic networks has been introduced in this paper. The introduced method (EBDM) circumvents the model order selection step for all the modules that are of primary interest to the experimenter, but still need to be identified in order to get a consistent estimate of the target module. Furthermore, by using regularized nonparametric methods, the number of parameters to be estimated is greatly reduced, with a clear benefit in terms of mean square error of the estimated target module. Numerical experiments performed with a dynamic network example illustrate the potentials of the developed method on comparison with the already available methods. The developed method provides better estimates and a reduced variance is observed in the identified model due to the integration of the regularization approach in the method.

REFERENCES

APPENDIX

Let $D_1 \in \mathbb{R}^{N^2 \times N}$ and $D_2 \in \mathbb{R}^{N^2 \times N}$ be two matrices such that, for any vector $w \in \mathbb{R}^N$, $D_1 w = \text{vec}(W)$, where $W$ is the Toeplitz matrix of $w$, and $D_2 w = \text{vec}(W^T)$. Let us define $\tilde{s}(n) \in \mathbb{R}^N$ be a vector such that, if $N \leq l$, $\tilde{s}(n)$ is the vector of first $N$ elements of $s(n)$ and if $N > l$, $\tilde{s}(n)$ is a vector with the first $l$ elements equal to $s(n)$ and the remaining ones equal to 0. Let $\tilde{S}(n), \tilde{W}_i \in \mathbb{R}^{N \times N}$ be the Toeplitz matrix of $\tilde{s}(n)$ and $\tilde{w}_i$ respectively. Then

$$X = \begin{bmatrix} W_{11} & W_{12} & \cdots & W_{1p} \end{bmatrix}, \quad \tilde{y}(n) = \tilde{S}(n)\tilde{W}_i$$

and $Z = \begin{bmatrix} \tilde{W}_1 & 0 & 0 & \cdots & 0 \end{bmatrix} \in \mathbb{R}^{N^2 \times (p+1)^2}$. Then we have

$$\tilde{A}(n) = [W_i^T \tilde{W}_i + D_1^T (Z \tilde{S}(n) Z^T \otimes I_N) D_1 + 2W_i^T \tilde{S}(n)]$$

and

$$\tilde{b}(n) = \begin{bmatrix} w_1^T \tilde{W}_1 + w_2^T \tilde{y}(n) - \tilde{s}(n)^T X^T W_i \\
- \frac{1}{2} \text{vec}(Z \tilde{S}(n)^T Z^T D_2) - \frac{1}{2} \text{vec}(X \tilde{S}(n)^T Z^T D_1)^T \end{bmatrix}^T.$$
