Abstract—Component characterization is fundamental for understanding the limits of optical devices, sub-systems and transmission systems. With the introduction of space division multiplexing in optical fiber transmission systems, new impairments such as mode dependent loss and differential mode dispersion arise. Spatially-diverse optical vector network analyzers are capable of measuring these characteristics in a fast single sweep over a very large bandwidth. As result of this large bandwidth, these analyzers are sensitive to differential chromatic dispersion within the interferometric measurement setup. This work discusses the influence and compensation of differential chromatic dispersion in such systems. Partial chromatic dispersion compensation is demonstrated to improve the representation and accuracy of impulse response measurements obtained from optical vector network analyzers for fibers and components with large differential chromatic dispersion. Analysis of a 39 core few-mode multi-core fiber is discussed, reporting variances of -2.9 ps/nm to -0.1 ps/nm, and 0.6 ps/nm to 6.9 ps/nm for the two mode groups, respectively, between the few-mode cores. A correlation with the total impulse response is observed. Furthermore, a maximum propagation skew of 20 ns between cores is observed after 13.6 km.

Index Terms—Space division multiplexing, optical vector network analysis, mode dependent loss, differential mode dispersion, device characterization, component analysis.

I. INTRODUCTION

Optical communication technology has advanced rapidly in recent years, supporting our increasingly information-driven society. The main prognosis is that demand will exceed the available capacity in the widely deployed single-mode fiber based systems in the near future [1], [2]. As a consequence, research in space-division multiplexing (SDM) has demonstrated transmission rates beyond 10 Pbit/s by exploiting multiple spatial channels in a single fiber [3]. Spatial multiplicity can be realized by exciting multiple spatial modes within a single few-mode or multi-mode core [4]–[7], transmitting over multiple cores in a single cladding [8], or by a combination of core and mode multiplexing [3], [9], [10].

The key to unlocking the potential capacity in SDM transmission systems is the characterization of individual components and sub-systems, as well as understanding the impairments introduced by those. One performance limiting effect are differences in losses and gains between the spatial channels, referred to as mode dependent loss (MDL). Components with large MDL can reduce the total system capacity, or, in extreme cases, can lead to channel outage [11]. Compensating this impairment is challenging, thus minimizing MDL must be mainly addressed in component design and manufacturing. Next to the different losses, the spatial channels propagate at different speeds through the system. A large variation between the modal group delays, or differential mode delay (DMD), leads to an increase of the impulse response duration, which in turn increases the memory required for the multiple-input multiple-output (MIMO) digital signal processing (DSP) algorithms employed to compensate mode mixing [12] and causes equalization enhanced phase noise [13].

Measurements for both MDL and differential group delay (DGD) can be quantified by the DSP algorithms in transmission experiments. Besides the large and expensive setup required, the measured bandwidth is typically limited to a single wavelength channel at a time. Hence, measuring the full C- or L-band for a temporally unstable system is challenging. Optical vector network analysis (OVNA) is a proven technique for component characterization over an extensive wavelength range in a single fast sweep measurement [14]–[18]. Such systems, based on swept wavelength interferometry (SWI)
employ a swept laser source that is fed to an interferometric structure, resulting in a fringe pattern dependent on the laser tuning rate and interferometer arm length differences. A device under test (DUT), placed in one of the arms will affect the interference pattern according to its transfer function matrix $H(\omega)$. From this interference pattern, the $2 \times 2$ Jones matrix of a single-mode component can be extracted. Subsequently, linear device parameters such as insertion loss (IL), group delay (GD), chromatic dispersion (CD), polarization dependent loss (PDL) and polarization mode dispersion (PMD) can be obtained from this matrix. The time-windowing technique proposed for measuring multi-port devices [17], can be applied to capture the $2M \times 2N$ transfer matrices of SDM components [15], [16], [19]. To measure a $2M \times 2N$ transfer matrix, an M-port splitter and an N-port combiner are required. The inherent power losses of the components challenge system scalability to a high number of modes. This especially holds for coupled spatial channels, such as modes in a few-mode fiber (FMF). Requirements for multi-core fiber (MCF) are slightly relaxed, as the crosstalk between the cores is typically designed to be small. Consequently, each core can be measured independently, reducing the splitting dimension and hence losses of the system. In addition to the previously mentioned linear device parameters, their multi-dimensional variants for SDM systems, i.e., MDL and DGD, can be calculated from the transfer function matrix.

In this work, we extend the detailed discussion on optical vector network analyzer (OVNA) for SDM components given in [16], by addressing the measurement procedure of the phase derived properties GD and CD. Both measured quantities include parts introduced by the DUT, and parts originating from the different interferometer lengths introduced to measure multi-port components. A residual contribution related to the mismatch with the reference arm is common to all matrix elements of transfer function matrix $H(\omega)$, and can be estimated. Similar to digital CD compensation in coherent optical transmission, this undesired dispersion can be removed with DSP, improving the accuracy of impulse response duration measurements. CD compensation is particularly beneficial for characterization of longer components, such as fiber. Furthermore, digital CD compensation is demonstrated to relax the requirement of matching interferometer arm lengths.

Optical vector network analysis of a large core-count few-mode multi-core fiber (FM-MCF) shows a large difference between the cores [20]. A detailed analysis of the impulse response duration and wavelength dependent dispersion is performed, reporting impulse response durations between 0.6 ns and 3.0 ns. Differential CD with respect to a single-mode core within the FM-MCF is $-2.9$ ps/nm to $-0.1$ ps/nm for the LP$_{01}$ and 0.6 ps/nm to $6.9$ ps/nm for the LP$_{11}$ mode groups, respectively. Partial compensation is applied on the individual mode groups, to remove the spreading of the impulse response induced by CD, improving the accuracy of modal dispersion estimates. Furthermore, difference in group delay of the few-mode cores with respect to the single mode core up to 20 ns are observed.

The remainder of this article is structured as follows: Section II introduces the hardware system and DSP required for characterization of SDM components using a spatially-diverse OVNA mainly focused on the measurement of wavelength dependent dispersion. The digital CD compensation and its impact on OVNA measurements is also discussed here. In Section III, a 39-core 3-mode FM-MCF is analyzed using OVNA. Finally, Section IV concludes the article.

II. DESCRIPTION OF A SPATIALLY-DIVERSE OPTICAL VECTOR NETWORK ANALYZER

A comprehensive description of spatially diverse optical vector network analyzers is given in [16]. The presented analysis is based on the group delay, derived from the frequency dependent propagation constant of the optical field, but ignores any higher order terms. This assumption is accurate when these effects are negligibly small, such as for slow sweeping rates and short device lengths. However, for optical vector network analysis of long fibers, higher order transmission effects captured within the propagation constant have to be taken into account.

The swept tunable laser (STL) source of the spatially-diverse OVNA, depicted in Fig. 1 produces an optical field:

$$ E_{STL}(t) = A_{STL}(t)e^{-j\omega(t)t}p_{STL}, $$

where $A_{STL}$ is the complex amplitude and $p_{STL}$ is the polarization state at the output of the STL. The angular frequency $\omega(t) = 2\pi c/(\lambda_s + \nu(t)t)$ is the result of the sweep
starting at \( \lambda_0 \) with a sweep rate of \( \nu(t) \). After propagation through an optical fiber of length \( z \), the field is given by:

\[
E(z,t) = A(z,t)e^{-j\omega t} e^{-j\beta(\omega)z} p_z,
\]

where \( \beta(\omega) \) is the frequency dependent propagation constant, and \( p_z \) is the polarization vector at point \( z \). Analogue to the derivation in [16], but with the inclusion of the propagation constant \( \beta \), the expression for one of the photocurrents from the polarization diverse receiver is given by:

\[
i_s = R|A|^2 \sqrt{\kappa} \sqrt{1 - \kappa} \sum_{k,l=1}^{N} \text{Re} \left[ \left( s_1 \hat{H}_{2k-1,2l-1} + s_2 \hat{H}_{2k,2l-1} \right) e^{-j\beta(z_{out,k}+z_{in,l}+z-R) + \omega(\tau+t)} \right] + \left( s_1 \hat{H}_{2k-1,2l+1} + s_2 \hat{H}_{2k,2l+1} \right) e^{-j\beta(z_{out,k}+z_{in,l}+z_p-R) + \omega(\tau+t)} \right],
\]

where \( \kappa \) denotes the asymmetrical beam-splitting ratio at the source, \( R \) denotes the sensitivity of the square law photodetectors, and \( z \) denote the fiber lengths in the system. The transfer function elements are denoted as \( \hat{H}_{k,l} \), where \( k \) and \( l \) represent the inputs and outputs of the DUT. The photo-current of the other detector is found by replacing the polarization vector \( s \) with the orthogonal vector \( p \) of the polarization beam combiner (PBC) in the polarization diverse receiver. Note that all contributions related to the delay lines \( \tau_{in}, \tau_{out} \), and \( \tau_{ref} \) can be calibrated out by reference measurements taken for the back-to-back configuration of the system, i.e., directly connecting all possible combinations of input delay lines with every output delay lines. However, the delay associated with the path length difference of DUT and reference arm, denoted by \( z_r \), changes for each DUT is not included in this calibration. The contribution of \( z_r \) is decomposed by approximating the propagation constant \( \beta \) with a Taylor expansion around \( \omega_0 \):

\[
\beta(\omega_0) = \sum_{n=0}^{\infty} \frac{\beta^{(n)}(\omega_0)}{n!} (\omega - \omega_0)^n,
\]

where \( \beta^{(n)}(\omega_0) \) denotes the \( n \)th derivative of \( \beta \) with respect to \( \omega \) evaluated at \( \omega_0 \), and \( n! \) is the factorial of \( n \). The first element of the sum \( (n = 0) \), produces a constant phase factor independent of the angular frequency, and thus can be neglected for this application. The contribution of \( n = 1 \) is related to the group delay \( \tau_z \) associated with path length \( z \), which translates to a frequency shift. This property is exploited to detect multiple transfer functions simultaneously in the polarization and space diverse OVNA setup. The group velocity dispersion (GVD) or CD described by \( \beta^{(2)}(\omega) \), introduces pulse broadening as result of different propagation speeds of spectral components. Since it is difficult to distinguish different types of dispersion within impulse response graphs, compensating the differential CD with respect to the reference arm can improve modal dispersion estimations from these types of graphs. Optionally, higher order effects described by \( \beta \) can be taken into account. However, from the performed measurements, higher order propagation effects deemed small enough to be of no relevance for modal dispersion estimation in few-mode fibers covered in this work. Hence, no additional higher order propagation effects are considered.

### A. Digital signal processing for optical vector network analysis

The first step in the DSP chain, which is depicted in Fig. 1, compensates the power fading related to the wavelength dependent polarization changes in the reference arm [21]. A moving average filter based on the polarized reference signal is calculated and subtracted from the two data signals.

The next module, converts the non-linear wavelength sweep to a linear frequency sweep by extracting new sample points from the received signal of the auxiliary clock interferometer. A bandpass-filter is applied around the expected clock frequency before detecting all zero crossings of the signal. The resulting sampling vector is upscaled, applied and applied to both data channels to obtain waveforms linearly spaced in frequency. In the spectra, obtained via FFT, the impulse response elements \( h_{kl} \) are found at the positions corresponding to the fiber delay \( \tau_p, \tau_{in}, \tau_{out} \), and \( \tau_{ref} \). Each element is selected by applying a windowing function. A flat top windows with sharp edges is applied to reduce ringing due to edge effects, while preserving the device impulse response in the center. Finally the frequency response elements \( \hat{H}_{kl}(\omega) \) are found by taking the iFFT of \( h_{kl}(t) \). Note that in the windowing process, the optical frequency sample spacing is reduced to one over the duration of the window.

From \( \hat{H}(\omega) \), both MDL and IL can be retrieved via singular value decomposition at every frequency [11], [15], [16]. The resulting \( \lambda_i(\omega) \) are the channel gains of the eigenmodes of the DUT. The IL is calculated as the mean of the \( |\lambda_i(\omega)|^2 \). Taking the ratio between largest and smallest singular value returns the MDL.

Next to the singular value analysis of \( \hat{H}(\omega) \), an eigenvalue analysis on \( \hat{H}(\omega + \delta \omega) \hat{H}(\omega)^{-1} \) can be performed, from which the group delays \( \tau_g \) and DMD of the principal modes are obtained [11]. Taking the derivative of this group delays with respect to wavelength leads to the GVD of the principal modes. Alternatively, the DMD can also be obtained directly from the impulse response matrix \( h(t) \) by measuring the delay time between mode peaks. This estimation can be performed on the individual matrix elements \( h_{ij}(t) \) or in a single estimation on the sum of the squared elements: \( \sum |h_{ij}|^2 \).

Note that both estimations cover the complete measurable range of the OVNA, and thus for components with strong wavelength dependent behaviour, i.e., devices with large differential CD, the impulse response duration will be overestimated. For this reason, a visual representation covering both time and frequency behaviour in a single graph is preferred. Modes and mode groups are generally easier to recognize in such spectrograms, allowing labeling of the mode groups. From these graphs, not only DMD estimations can be derived, they also visualize the wavelength dependent change of dispersion. One notable disadvantage of these spectrograms is their reduced visual resolution as a result of using a color-scale to represent transmission intensity compared to standard lines in an impulse response plot. Analog to the impulse response,
Figure 2: Impulse response of a single-mode fiber core before (a) and after (b) compensating differential chromatic dispersion.

polarization or mode collapsed versions of these graphs can be obtained by summing matrix elements.

B. Digital chromatic dispersion compensation in optical vector network analyzers

As described at the beginning of this section, the obtained transfer function matrix includes propagation effects related to the differential path length of DUT and reference arm, denoted by $\tau_r$. In order to improve modal dispersion estimation from impulse response graphs, additional sources of dispersion must be removed from the calculated transfer function matrix. Hence, digital dispersion compensation, similar to coherent optical communication, is applied [22]. The following digital filter with a complementary amount of dispersion is designed and applied to the signals:

$$H_{CD}(z, \omega) = \exp\left(-\frac{j D \lambda_0^2}{4 \pi c} \omega^2\right), \quad (5)$$

where $\lambda_0$ is the center wavelength of the sweep, $c$ denotes the speed of light, and $D$ denotes the accumulated CD over a path length $z$.

An example of the effect of CD compensation on impulse response measurements with OVNA is shown in Fig. 2, which shows the impulse response of a single mode fiber core. From OVNA a differential CD of 16.4 ps/nm with the reference arm was observed. This value is verified by optical time-domain reflectometry (OTDR) measurements. This differential CD is mainly attributed to the 46 m length differences of DUT and standard single-mode fiber (SSMF) span employed as reference. As can be seen in Fig. 2, the impulse response spread is significantly reduced by applying a filter designed with −16.4 ps/nm dispersion.

III. ANALYSIS OF A 39-CORE FEW-MODE FIBER

This section covers the analysis of a 39 core FM-MCF using OVNA by exploiting the setup in Fig. 1. A detailed depiction of the DUT section of the setup is shown in Fig. 3a. After polarization multiplexing with a delay $\tau_{pol} = 50$ ns, three input delays $\tau_{in,k} = k \cdot 4.5$ ns for the modes are placed at the input of a laser inscribed glass mode-multiplexer. The few-mode output pigtail is switched between the core multiplexer input ports, which are equipped with specially designed SC/UPC few-mode connectors [23]. At the other side of the 13.6 km fiber, a reciprocal configuration including mode- and core-demultiplexer is configured with delays $\tau_{out,l} = l \cdot 45$ ns. Note that $\tau_{in,0}$ and $\tau_{out,0}$ are typically omitted in similar setups. However, for this configuration, where the reference arm has exactly the same length as the DUT, additional delay was introduced to avoid the risk of overlapping signals in the spectrogram. The transfer function matrix for each core is obtained in a single sweep, at a rate of 100 nm/s ranging from 1530 nm to 1570 nm. All signals are digitized by a real-time oscilloscope sampling at 10 MSa/s, followed by the DSP steps of the schematic in Fig. 1. The optical sample rate produced by the 20 m delay in the reference clock interferometer is 16 times digitally up-sampled before re-timing the measurement channels.

A. Large core-count few-mode fiber

The core layout of the 312 μm cladding diameter fiber under test is shown in Fig. 3b. The cores are placed with a minimum pitch of 40 μm on a three-ring layout with radii $r_1 = 41 \mu m$, $r_2 = 79 \mu m$, and $r_3 = 127 \mu m$. 38 of the cores are of the trench assisted graded-index type, designed to support 3-modes each. The last core supports only the fundamental mode, and thus must be removed from the calculated transfer function matrix. Note that $\lambda_0$ is the center wavelength of the sweep, $c$ denotes the speed of light, and $D$ denotes the accumulated CD over a path length $z$.

Reference arm Reference arm

Figure 3: (a) DUT section placed in setup of Fig. 1. The reference arm is guided through the single mode core, core 39. (b) Core layout of the 39 core fiber and the refractive index profile of the 3-mode and single-mode cores.
Figure 4: Spectrograms for all 38 few-mode cores, with enlarged images for cores 1, 5, 22 and 31. Differential CD is demonstrated for core 9. (a) spectrogram without compensation, (b) −2.3 ps/nm compensation for LP01 mode, and (c) 2.8 ps/nm compensation for LP11 modes.

Slopes differ strongly between the cores, they can be grouped in two sets based on the direction of the slope. For every core, two closely confined lines with a negative slope are observed. Due to the small differential group delay between them, these temporal lines are linked to the two polarization states of the fundamental mode. The other set contains four lines, which correspond to the degenerate modes of the LP11 group. Note that the differential group delay varies strongly between the cores. The spectrograms of cores 1, 5, 22 and 31 are selected as examples to discuss recognizable features. Therefore, enlarged views of these spectrograms are included in Fig. 4.

In the spectrogram of core 5, both groups slightly diverge but overlap for the 40 nm of analyzed wavelength range, indicating the mode coupling between the groups is stronger and DMD is smaller compared to the other depicted cores in Fig. 4. The spectrogram of core 22 shows a clear separation between the mode groups. Based on the dispersion slope of the lines it is presumed that the center line represents the LP01 mode, which is surrounded by the degenerate LP11 modes. The wavelength dependent impulse response spread for this core, in this 40 nm range is completely determined by the LP11 mode. Core 31 also shows a noticeable amount of differential mode group delay (DMGD), but there is a clear overlap between the fundamental mode and one of the LP11 modes. The last type of spectrogram is illustrated by core 1, which shows a clean separation between the two mode groups with a significant modal dispersion of the four degenerate LP11 modes.

From the spectrogram arrangement to the core layout in Fig. 3b, it is observed that the cores on the left half of the outer ring closely resemble the behavior depicted in the spectrogram for core 31 and the right half of that circle behaves similar to core 22. A similarly low DMD characteristic as in core 5 (Fig. 4a) is also observed for core 12. Similar to core 1, a larger impulse response spread for the LP11 modes for cores on the inner circles is observed. The strongly varying behavior of the few-mode cores is likely related to imperfections of the cores.

Figure 5: (Differential) chromatic dispersion for all modes and cores. The values of the single-mode core, and single-mode fiber (SMF) link are included for reference.
the manufacturing process, resulting in deviations from the intended design.

Furthermore, observe the slope of the lines from all spectrograms. For all cores, the two mode groups have a wavelength dependent slope in opposite directions. The slope for both lines was estimated and the resulting CD for each core is given in Fig. 5. The left axis shows the differential CD with respect to the single-mode core, and the actual CD in ps/(nm·km) is given on the right. This last value was obtained by measuring the CD of the single-mode core using a fiber analyzer based on OTDR, the SMF span used as a reference to characterize the single-mode core with the OVNA is also included in the graph. The graph shows that in all fiber cores, the fundamental mode has slightly less CD with respect to SMF, whereas the other mode-group has a larger CD value with a larger spread among the cores.

The measured CD values are mapped to the core-layout in Fig. 6a, where each half of the circle represents one of the mode groups. This measurement is compared to the previously analyzed impulse response duration in [28], shown in Fig. 6b. A strong correlation between the color intensities of the graph can be observed, linking the longer impulse response duration to a larger differential CD value. The longest impulse responses and highest CD values are measured for the cores on the left half of the outer ring (core 25-35).

CD compensation based on the measured values has been applied on the cores to isolate the DMGD. Given the different amounts of dispersion for the individual mode groups, only one of the groups can be fully compensated. As can be observed in the spectrograms for core 9 in Fig. 4, where CD compensation is applied to each individual mode group by applying -2.3 ps/nm (Fig. 4b) and 2.8 ps/nm (Fig. 4c) CD compensation receptively. Alternatively, an intermediate value can be chosen for partial compensation of both mode groups. By removing the wavelength dependent dispersion, the summed impulse responses are narrower, and give a better indication of the modal dispersion.

For each core, a singular value decomposition (SVD) is performed on the transfer function matrix at each frequency. Subsequently, the IL is calculated at 50 GHz resolution. Figure 7 shows the average, minimum, and maximum IL in the band ranging from 1530 nm to 1570 nm. An average IL of 8.7 dB is observed between all the few-mode cores, with high insertion losses for cores 10, 14, 15, 25 and 32. The obtained IL is in agreement with the system IL measured for the transmission experiment in [23]. Note that the losses includes contributions of the PL mode-multiplexers. Therefore, the IL of the PL pair is measured with the OVNA, from which an average IL of 2.8 dB per PL is obtained. Furthermore, a similar variation of losses within the 40 nm range is observed.

For the evaluated DUT, the largest contribution of MDL is to be expected from the spatial multiplexers. Hence, the MDL of the 3-mode multiplexer pair is measured first. An average MDL of 20.1 dB for 50 GHz sub-bands within the 40 nm analyzed bandwidth was found. The measured system MDL of both mode- and core-multiplexers, and 13.6 km FM-MCF was measured to be all below 25 dB. Since this result is dominated by the large contribution of the spatial multiplexers and the compound MDL of multiple concatenated elements in the weak coupling regime strongly depends on the relative alignment of their respective principle modes, no statement on the MDL of the fiber can be made.

An important parameter for employing the FM-MCF with single-mode core for self-coherent detection is the skew between few-mode cores and single-mode core. Figure 6d, shows the group delay difference of each few-mode core with respect to the single-mode core. A skew ranging from 173.3 ns to
190.7 ns, with an average of 182.2 ns is observed. Note that the skew is clearly the smallest on one side of the fiber, and largest on the opposite side. This gradient is likely attributed to the spooling on the fiber, which result in compression of the inner cores and stretching of the outer cores.

IV. Conclusions

In this work, we have discussed the influence of differential chromatic dispersion in optical vector network analyzers. Chromatic dispersion compensation is demonstrated for a single-mode core and partially for few-mode cores in a multicore fiber.

Optical vector network analysis is employed for the characterization of a 39 core few-mode fiber, showing large variations in temporal response between the cores. Which demonstrates the challenging fabrication of long, homogeneous large-core count few-mode fibers. Differential chromatic dispersion variations between the cores of ~2.9 ps/nm to 0.1 ps/nm, and 0.6 ps/nm to 6.9 ps/nm for the two mode groups respectively were observed. These variances show strong correlations with the measured impulse response durations of 0.6 ns to 3.0 ns. Furthermore, an approximate 20 ns variation in differential group delay of the few-mode cores and single-mode core was observed. Its distribution suggests this is mainly caused by the spooling of the fiber, which compresses the inner cores.

It is expected that through improved techniques for accurate optical vector network analysis of components, fibers and subsystems for space division multiplexed transmission, improved development of devices and fibers will pave the way towards actual deployment of SDM in the field.
