\textbf{A B S T R A C T}

Pressure ulcers (PUs) represent a substantial burden to both patients and healthcare providers. Accordingly, effective prevention strategies should follow early detection of PUs. Anaerobic metabolites, such as lactate and pyruvate, are promising noninvasive biomarkers indicative of tissue ischaemia, one of the major mechanisms leading to PU development. The aim of this study was to investigate if the temporal release profile of these metabolites in sweat and sebum is sensitive to detect local tissue changes resulting from prolonged mechanical loads.

The sacrum of healthy volunteers was subjected to two different loading protocols. After a baseline measurement, the left and right side of the sacrum were subjected to continuous and intermittent loading regimen, respectively, at a pressure of 100 mmHg. Biomarker samples were collected every 20 min, with a total experimental time of 140 min. Sweat was collected at 37°C and 80% relative humidity, and sebum at ambient conditions, from 11 to 13 volunteers, respectively. Both samples were analysed for lactate and pyruvate concentrations using ultra-high performance supercritical fluid chromatography mass spectrometry. Prior to analysis metabolite concentrations were normalized to individual baseline levels and, in the case of sweat, additional normalization was performed to an unloaded control site to account for fatigue of sweat glands.

Although substantial variability was present, the temporal release profiles of both sweat and sebum metabolites reflected the applied loading regimen with increased levels upon load application, and recovery to baseline levels following load removal. Highest relative increases were 20% and 30% for sweat lactate and pyruvate, respectively, and 41% for sebum lactate. Sebum pyruvate was not present in quantifiable amounts. There was a linear correlation between the individual responses to intermittent and continuous loading.

The present study revealed that metabolite biomarkers in both sweat and sebum were sensitive to the application of mechanical loads, indicative of local ischaemia within skin and soft tissues. Similar trends in metabolic biomarkers were observed in response to intermittent and continuous loading regimes in both sweat and sebum. Metabolites represent a potential means to monitor the health of loaded skin and soft tissues informing timely interventions of PU prevention.

1. Introduction

A pressure ulcer (PU) has been defined in an International consensus as “a localized injury to skin and/or underlying tissue, usually over a bony prominence, as a result of prolonged mechanical loading in the form of pressure, or pressure in combination with shear” [29]. Pressure ulcers represent a substantial burden to the healthcare providers with associated costs for prevention and treatment of these chronic wounds [10]. More importantly, developing a PU can have substantial effects on quality of life [43] and associated complications can potentially prove lethal [37].

The aetiology of a PU involves two main damage pathways [31], both related to the duration and magnitude of internal tissue deformation resulting from externally applied load [21,30]. Thus direct deformation damage, resulting from high internal deformations can lead to cell damage within minutes, involving rupture of the cell membrane and cytoskeleton disruption [22,30]. Alternatively, ischaemic damage can occur over a period of several hours, as a result of moderate internal tissue deformation causing the occlusion of blood and lymph vessels. This occlusion results in impaired transport of vital nutrients including oxygen into the tissue, forcing cells to switch from an aerobic to anaerobic metabolism under the hypoxic conditions. Moreover, the occluded lymph vessels are unable to remove metabolic waste products, which accumulate in the cellular environment, resulting in a damaging decrease in local pH [23]. The subsequent removal of mechanical load leads to tissue reperfusion, supplying oxygen and other nutrients to the tissue. However, this may result in an overproduction of oxygen-derived free radicals [24], which have been associated with further tissue damage.

PU risk assessment is routinely performed using tools such as the Braden, Norton or Waterlow scales in combination with clinical experience [28]. Although these subjective measures can predict PU...
occurrence to some extent, they often lead to inefficient use of preventive measures [41]. Moreover, identifying patients at risk is complicated due to individual variability in tissue tolerance to mechanical loading, which is an intrinsically determined property. Similar issues exist with the early detection of PUs in a clinical setting. The current gold standard is visual inspection and palpation [29], although the former is unable to detect a visible blanching response in darkly pigmented skin [39]. Thus, there is a need for an objective tool to monitor the status of loaded tissues, which reflects the local pathophysiological response in vulnerable tissue sites.

The analysis of biomarkers, which can be collected from a range of body fluids, including urine, blood, sweat and sebum, has been proposed as a strategy to assess tissue status in an objective manner [2]. Potential PU detection methods using biomarkers have been reported, typically monitoring actual tissue breakdown or the response to known loads, involving inflammatory cytokines [5,9,18,42,46,48,49], C-reactive protein [17,25], myoglobin [25,45], troponin [45] and purines [1]. Indeed, the authors recently demonstrated the use of non-invasive inflammatory biomarkers as a potential indicator of pressure-induced tissue damage [42].

Another promising approach is to use noninvasive biomarkers as early indicators of ischaemic damage. Suitable candidates are the metabolic waste products, lactate and pyruvate, which are produced through glycolysis, and thus provide indicators for anaerobic cell metabolism. Indeed sweat lactate has been identified as a potential indicator of skin ischaemia, first reported by van Heynigen and Weiner in 1952 [47], who observed an increase in concentration upon arterial occlusion of the arm. Subsequent studies have shown elevated sweat lactate concentrations during periods of load-induced ischaemia in a group of able-bodied subjects [12] and those with disability [35]. In addition, studies have combined the analysis of sweat lactate with transcutaneous oxygen tissue gas (TcPO2), revealing a significant correlation after the latter exceeded a threshold reduction value of 60% when compared to unloaded basal values [20]. The application of sampling sebum lactate in a clinical scenario was tested by Hemmes et al. [18], where the temporal release was monitored at the sacrum, with a cohort of healthy volunteers lying on a rigid spineboard. Lactate was found to increase with prolonged exposure to pressure, and to decrease in the unloaded prone position, although there was no significant relationship with pressure magnitude.

More recently, technological advances have enabled the simultaneous quantification of multiple metabolites in sweat [19]. The exploration of other relevant metabolites and metabolite ratios is therefore possible. Indeed, the lactate/pyruvate ratio (L/P) has proved a useful indicator for severity and prognosis of ischemic related diseases, including acute liver failure [11], myocardial injury [6] and traumatic brain injury [36]. However, this key metabolite ratio has not been investigated in the context of pressure-induced skin damage. Accordingly, the present study addressed the following questions:

- Is the temporal release profile of anaerobic metabolites in sweat and sebum representative for local tissue status?
- Is there a difference in the response profiles to intermittent and continuous loading?

The aims were achieved by examining the temporal profiles of metabolic waste products resulting from two distinct loading regimens at the sacrum of a cohort of healthy volunteers. Metabolic concentrations of lactate and pyruvate in sweat, and lactate in sebum were quantified using ultrahigh performance supercritical fluid chromatography-mass spectrometry (UHPSFC-MS).

2. Materials and methods

2.1. Participants

The participants were recruited from the local university population. The protocol was approved by the ethics committee of the University of Southampton (ERGO–FOHS–19647), and informed written consent was obtained from the participants before testing and for the publication of the images.

2.2. Test equipment

The test equipment has been recently described by Soetens et al. [42]. To review briefly, a double sided custom-made loading system was employed using two independent cylindrical weights (100 mmHg, ø36 mm) suspended from a frame mounted over a hospital bed. Sebum was collected using Sebutape (CuDerm, Dallas, TX, USA). Sweat was collected on circular filter paper pads (Whatman Chromatography, Whatman paper, Maidstone, UK) which were 40 mm in diameter, covered with a sheet of Parafilm M (Bemis NA, Neenah, WI, USA) to prevent evaporation during the collection period. The fluid capacity of each filter paper was 240 μL.

2.3. Test protocol

The experimental protocol described by Soetens et al. [42] was performed at both ambient conditions (temp. 20 ± 2 °C, RH 40 ± 5%), and in an environmental chamber (temp. 37 ± 1 °C, RH 80 ± 5%), to obtain sebum and sweat samples, respectively. To review briefly, while participants remained in a prone lying position, the left and right side of the sacrum were subjected to the different loading regimens using two independent cylindrical weights (diameter 35 mm) suspended from a frame mounted over a hospital bed. This was equivalent to a significant pressure of 100 mmHg, similar in magnitude to that used in previous studies [20,35]. The lower back acted as an unloaded control site (Fig. 1). Mild erythema in the absence of pain was observed in some of the participants following the intermittent loading regimen. The skin was checked for blanching to ensure no skin damage had resulted from the 2-h test period.

Samples from each site were collected every 20 min, including an

![Fig. 1. Picture of the experimental setup in the environmental chamber (left), with the participant lying in prone position, while the left and right side of the sacrum were subjected to different loading regimen. Filter paper pads were applied to obtain sweat samples on three measurement sites (right): left sacrum (continuous loading), right sacrum (intermittent loading) and lower back (unloaded control).](image-url)
initial acclimatisation period, loading periods and offloading periods, resulting in a total experimental time of 2 h and 20 min. The acclimatisation period provided baseline values, during which all three sites remained completely unloaded. Subsequently, the left and right side of the sacrum were subjected to continuous and intermittent loading, respectively (Fig. 2).

Sebutapes were applied to the skin for 2 min, using a gloved hand and tweezers to avoid cross contamination. The samples were coded and stored immediately at −80 °C.

By contrast, sweat was collected on the circular filter paper pads continuously during each loading phase. At the end of each 20 min period, the pads were removed and placed in self-standing 30 mL centrifuge tubes (Sterilin 128B/FS, Thermo Scientific, Waltham, MA, USA). The yield was measured gravimetrically and each pad was centrifuged at 3000 g for 10 min to extract the sweat. In the case of an insufficient yield (<160 µL), reverse osmosis water was applied to the pad prior to centrifuging to increase the volume with a maximum dilution factor of 25. Once collected, the sweat samples were stored at −80 °C.

2.4. Biochemical analysis

Sebum recovery was performed following an optimized protocol based on Perkins et al. [33]. The Sebutapes were submerged in 2 mL of phosphate buffered saline (PBS, Sigma-Aldrich Co., St. Louis, MO, USA) with the addition of 0.05% TWEEN20 (Sigma-Aldrich Co., St. Louis, MO, USA). To optimize protein recovery, the tubes were subsequently placed on a roller mixer for 1 h, sonicated for 10 min and individually vortexed for 2 min. The sweat samples were diluted 5 times with reverse osmosis water directly after thawing, vortexed briefly and mixed with a sterile pipette tip prior to analysis.

UHPFSC-MS was performed, as described by Herniman et al. [19], using an Acquity UPC² ultra performance convergence chromatograph (Waters, Milford, UK) with CO₂ as the supercritical fluid. A UPC² Torus Diol 3 x 100 mm, 1.7 µm column (Waters, Milford, MA, USA) was used with 50 mM ammonium acetate methanol/2% water modifier. The column temperature was 50 °C with an injection volume of 2 µL, elution flow rate of 1.5 mL/min, ABPR set at 15 MPa and methanol/1% HCOOH make-up flow solvent at 0.45 mL/min.

Positive (and negative ion) ESI mass spectra were recorded using a Waters SQD2 single quadrupole mass spectrometer (Waters, Wilmslow, UK), with capillary voltage 3.3 (−3.3) kV, cone voltage 20 (−20) V, extractor 3.0 (−3.0) V, source temperature 150 °C, desolvation temperature 500 °C, desolvation gas flow 650 L/h. Single ion recording for the protonated (deprotonated) molecules was used for all experiments. Data acquisition and processing were undertaken using MassLynx 4.1 (Waters, Milford, USA). Linearity for both lactate and pyruvate standards was excellent in the range of interest, 1–2500 ppm, with R² = 0.9976 and R² = 0.9970, respectively.

2.5. Data analysis

Statistical analysis was performed using IBM SPSS Statistics V23 (IBM Corporation, Armonk, NY, USA). Measured sweat lactate and pyruvate concentrations from the sacral loading sites were normalized to values of the unloaded site (lower back) for the equivalent test periods. Subsequently they were normalized to baseline in order to allow comparison of relative ratio changes between participants. Sebum lactate concentrations were only normalized to baseline for the same reason. Pairwise comparisons were tested for significance using, due to small sample sizes, the non-parametric Wilcoxon signed rank test. Data is presented using median (IQR) and the statistical significance level was set at p<0.05.

3. Results

3.1. Sweat metabolite study

Eleven healthy participants (5 males and 6 females) were included in the study investigating sweat metabolites. Their mean age was 28 years (range 21–36 years), mean height was 1.71 ± 0.08 m, mean weight was 72.7 ± 10.6 kg, with a corresponding body mass index of 24.7 ± 2.5 kg/m². Two participants were excluded from the analysis since their sweat rate was too low to obtain a sufficient yield for reliable analysis.

For the remaining participants the sweat yield was sufficient for analysis from the three test sites and remained fairly constant throughout the test period, as indicated in Table 1. The mean yields ranged between 140 and 245 µL, with the largest volumes produced in the control lower back site for each test period. In general, the first and last measurement showed lowest sweat rates.

A gradual decrease in the temporal release profile of both lactate and pyruvate concentrations was observed at all sites, as shown with their median absolute values in Fig. 3. Lactate concentrations decreased over 2-fold, whereas pyruvate concentrations decreased over 5-fold. Accordingly, the L/P ratio increased at all loading sites (Table 1), irrespective of loaded state, such that the differences between measurement periods were statistically significant (p < 0.05 in all cases). The absolute lactate concentrations were between 12.1 and 48.5 fold higher than the associated pyruvate concentrations.

In order to investigate the relative influence of load application, normalization to metabolite levels with respect to the unloaded control site was performed to remove the systemic effect of sweat gland fatigue. As a result, for both intermittent and continuous loading, the median normalized lactate and pyruvate levels reflect the applied temporal loading profile (Fig. 4). Although substantial variance in the metabolite expression was observed across the participants, it was evident for the majority of cases that there was an up-regulation of both metabolites.

![Fig. 2. Schematic of the experimental protocol, with intermittent (top) and continuous loading (bottom) regimens applied to the right and left side of the sacrum, respectively. Each regimen consists of 7 measurement periods of 20 min (bottom row), in which either loading (grey) or no loading (white) was applied. Samples of either sweat (filter paper) or sebum (Sebutape) were sampled at the beginning and end of each 20 min phase.](image-url)
immediately following the loading periods, which generally recovered to baseline levels during unloading. Close examination revealed that the highest increases were associated with continuous loading, with a 20% and 30% median increase in lactate and pyruvate values, respectively. When compared to baseline values, the levels were significantly (p < 0.05) up-regulated after 40 min of continuous loading for lactate, and at both 40 min and 1 h for pyruvate (Fig. 4b,d). In the case of sweat lactate, concentrations following load removal were lower than that at baseline i.e. median ratio < 1.

In a similar approach to a recent paper by the authors [42], the overall response from each individual was quantified in order to reveal inter-participant variability. This involved calculation of the median accumulated response during the 2 h load/unload periods for both regimens, as indicated with pyruvate for a single participant in Fig. 5.

The median values of lactate response to intermittent and continuous loading were 1.03 (0.84–1.36) and 1.11 (0.68–1.56), respectively. These associated differences were not statistically significant (Z = −0.089, p = 0.929). Equivalent findings were obtained for the pyruvate response (Z = −0.267, p = 0.790). However, correlation of the pyruvate responses to intermittent and continuous loading was statistically significant (p = 0.007), as indicated by the Spearman’s rank correlation test (Fig. 6). For lactate this correlation was less pronounced (p = 0.536, p = 0.086).

3.2. Sebum lactate

In the study investigating sebum lactate, thirteen healthy participants (7 males and 6 females) were included, with a mean age of 31 years (range 21–65 years), mean height of 1.72 ± 0.08 m, and mean weight of 73.3 ± 10.2 kg with a corresponding body mass index of 24.7 ± 2.3 kg/m².

The absolute concentrations of both lactate and pyruvate were found to be three orders of magnitude lower than those in sweat, with the latter not present in quantifiable amounts. Nonetheless, the up-regulation of lactate concentrations in µM reflected both temporal loading profiles, as shown in Fig. 7, although, as with sweat metabolites, large individual variability was evident.

The temporal lactate levels on the unloaded control site remained constant over all test periods, with no significant changes (Z = −0.357 to −0.764, p = 0.445 to 0.721). Therefore for a quantitative comparison of individuals, in contrast with the sweat data, only baseline normalization was performed for sebum lactate. During the intermittent regimen, the lactate levels increased upon load application, while load removal resulted in a recovery to baseline levels, with statistical significant differences evident in the first four test periods (Z = −2.691 to −3.040, p = 0.002 to 0.007). In the continuous loading regimen, application (Z = −2.411, p = 0.016) and removal (Z = −2.411, p = 0.016) of the load resulted in a significant changes in lactate values (Fig. 8). For the first refractory period in the intermittent loading regimen and the final refractory period in the continuous loading regimen, the measured lactate levels were significantly lower than baseline (p<0.05). The highest median increases to intermittent and continuous loading in separate periods were found to be 41% and 32%, respectively.

In a similar manner to the sweat metabolite data, the median accumulated response to both loading regimens was determined. The differences in median response of 0.98 (0.89–1.25) and 0.93 (0.81–1.14) for intermittent and continuous loading regimens, respectively, were not statistically significant (Z = −1.712, p = 0.087).

Although trends were evident, the correlation of lactate responses to intermittent and continuous loading was not statistically significant (Fig. 9), as shown by the Spearman correlation test (p = 0.434, p = 0.138).

4. Discussion

The current study examined the temporal release profile of sweat and sebum metabolites resulting from both intermittent and continuous loading. Its primary aim was to evaluate if the anaerobic metabolites in sweat and sebum were representative of local loaded tissue status.
Subsequently, the study revealed expression levels of lactate and pyruvate reflected the applied temporal loading profiles. Indeed, upon application of the two loading regimens normalized metabolite levels increased and load removal resulted in recovery to baseline levels in both sweat and sebum. Although testing was performed on a small group of healthy volunteers, the results suggest considerable potential for these biomarkers to be used as objective means to monitor the status of loaded skin and soft tissues.

The highest increases in sweat lactate and pyruvate were found to be 20% and 30% greater than baseline values, respectively. Similar findings from pre- and post-loaded studies have been reported. For example, Ferguson-Pell et al. [12] reported a 37% increase in sweat lactate after 30 min of loading at the volar forearm with 150 mmHg. A similar magnitude and period of loading using a uniaxial indenter yielded a 76% increase in sweat lactate [34]. In a study combining physical sensors with sweat biomarkers, Knight et al. [20] reported an increase of lactate concentrations by 29–39% as a result of sacral loading at interface pressures of 80–120 mmHg applied for a period of 60 min. This relative change in lactate concentration was also observed in the sacral region of a cohort of spinal cord injured, following a period of prolonged lying postures [35].

In contrast to previous studies, the gradual temporal decrease in sweat metabolite concentrations across both control and loaded test sites (Fig. 3) necessitated the need for normalization. Estimation of the L/P ratio revealed a monotonic temporal increase, on average from 13 to 38, irrespective of load application (Table 1). This might be attributed to fatigue of the local sweat glands, as suggested by Ferguson-Pell et al. [12]. This fatigue process represents a systemic effect, since it was also observed at the unloaded control site, as a direct result of the experimental conditions associated with the high sweat rates in the elevated ambient conditions.

It was therefore worthwhile to investigate if metabolic biomarkers could also be measured at lower ambient conditions, as previously described by Hemmes et al. [18]. In the current study, the sebum metabolite release profile was constant over the course of the experiment at the control site, reflecting limited fatigue of the sebaceous glands. Therefore, any changes observed over the loading sites can be attributed to the local tissue ischaemia, resulting from the applied loading. The relative increase in lactate levels, namely 42% for continuous loading, was lower than those reported by Hemmes et al. [18], which is probably due to the difference loading magnitude (100 mmHg vs. 240 mmHg). Although the absolute sebum lactate concentrations were
orders of magnitude lower than those in sweat, μm versus mM, respectively, the relative changes in normalized metabolites were indicative of the applied temporal loading profile, particularly associated with intermittent loading (Fig. 8). This is indicated by the statistical significant changes in lactate levels upon load application and removal. The present study therefore provides supporting evidence that sebum lactate can represent a promising biomarker for monitoring local tissue ischaemia under clinically relevant ambient conditions. The associated absolute metabolite concentrations were well within the performance characteristics of the UHPSFC-MS, making it a sensitive methodology to detect change.

In order to assess whether a difference is observed between the responses of each loading regimens, the metabolite profiles were quantified by the median accumulated response, which accounts for the median metabolite level during both loading and unloading regimes (2h). For both sweat metabolites and sebum lactate, no differences between intermittent and continuous loading were observed (Figs. 6 and 9). These findings suggest that the duration of load-induced ischaemia in the current study, namely either 3 × 20 min for intermittent or 60 min for continuous loading, was insufficient to reveal any benefits attributed to intermittent load relief.

The suitability of the metabolic biomarkers for the early detection of PU development needs further investigation. Previously, Stekelenburg et al. [44] reported that tissue damage in a rat model was not induced.
after 2 h of complete ischaemia. Considering both the magnitude and duration of loading in the current study, the applied loading regimens were not sufficient to cause tissue damage. Therefore, the current experimental protocol should be extended beyond 2 h with enhanced refractory periods. Alternatively, provided ethics are granted, the metabolite biomarker expression over grade I PUs could be sampled.

In line with previous studies [1,20,34,42], the cohort of able-bodied volunteers revealed considerable variability in biomarker expression, as indicated by the individual responses to intermittent and continuous loading regimens (Figs. 6 and 9). This might potentially be explained by the variability in individual tissue morphology. In order to identify sub-populations that are at particular risk, additional information is required regarding the relationship between the physiological and biochemical response to loading on an individual basis. As an example, the metabolite expression levels could be related to internal tissue deformation and perfusion, e.g. via transcutaneous gas measurement [20], on an individual basis. The loading device could be adapted to enable simultaneous measurement of mechanical and biochemical responses. For example, local tissue deformations and tissue perfusion could be assessed using photoacoustics, ultrasound and strain imaging [26]. Similarly, magnetic resonance imaging (MRI) has proven to be useful for this purpose in animal models [23,24,44].

Together with the inflammatory biomarkers from our previous study [42], both the ischaemic and inflammatory damage pathways can be monitored non-invasively. The current methodology enables monitoring of the biological response of the tissue with a high level of accuracy and high sensitivity to change. The causal link between changes in ischaemic and inflammatory biomarkers and skin damage need to be further explored, using temporal and spatial evaluations. The time over which biomaterials are sampled should incorporate the known physiological response to loading, including the changes in microvasculature (vasodilation) [3,13] and signalling pathways of pro- and anti-inflammatory biomarkers [16]. However, in order to gain clinical translation it must be adapted into a point-of-care biosensor capable of monitoring the temporal metabolism and inflammatory expression levels. However, such a development for an early detection of PUs with adequate sensitivity is not trivial. It is also recognized that the presence of moisture, e.g. sweat, in the local microclimate of a loaded interface is not desirable as it can contribute to the development of a PU [29]. However, in some specific cases excessive perspiration is common, such as the residual limb/socket interface during exercise, making sweat a readily available biofluid for biomarker analysis.

5. Conclusions

The present study suggests that metabolites in both sebum and sweat may have the potential to act as suitable biomarkers for the non-invasive detection of changes due to local ischaemia in periodically-loaded skin tissues. However, sweat metabolite levels required normalization to an unloaded control site to distinguish between systemic and local changes. Similar trends in metabolic biomarkers were observed in response to intermittent and continuous loading regimens in both sweat and sebum. This study supports previous study findings that metabolites can prove suitable biomarkers for the early detection physiological changes indicative of pressure ulcer risk induced by external mechanical loading.
