Dilution-induced gel-sol-gel-sol transitions by competitive supramolecular pathways in water

Lu Su1, Jesús Mosquera1, Mathijs F. J. Mabesoone1, Sandra M. C. Schoenmakers1, Cyprien Muller1, Marie E. J. Vleugels1, Shikha Dhiman1, Stefan Wijker1, Anja R. A. Palmans1, E. W. Meijer1,4*

Fascinating properties are displayed by synthetic multicomponent supramolecular systems that comprise a manifold of competitive interactions, thereby mimicking natural processes. We present the integration of two reentrant phase transitions based on an unexpected dilution-induced assembly process using supramolecular polymers and surfactants. The co-assembly of the water-soluble benzene-1,3,5-tricarboxamide (BTA-EG4) and a surfactant at a specific ratio yielded small-sized aggregates. These interactions were modeled using the competition between self-sorting and co-assembly of both components. The small-sized aggregates were transformed into supramolecular polymer networks by a twofold dilution in water without changing their ratio. Kinetic experiments show the in situ growth of micrometer-long fibers in the dilution process. We were able to create systems that undergo fully reversible hydrogel-solution-hydrogel-solution transitions upon dilution by introducing another orthogonal interaction.

The design of interactive and adaptive soft materials requires a complex composition of chemical components for which nature is often a source of inspiration (1). Multicomponent systems formed by multiple associative and dissociative interactions are key signatures of biological matter, but the competitive interplay of all these interactions makes the understanding of certain natural processes difficult (2, 3). Synthetic systems, because of their simplicity, can unravel some of these challenges while yielding new functionalities (4–7). Although this field is still in its infancy, several examples have highlighted its potential for applications in catalysis, electronics, and medicine (6–11), with the development of the lipid nanoparticle-encapsulated mRNA vaccine as an obvious successful highlight in this respect (12).

Liquid-liquid phase separations are often accompanied by the occurrence of reentrant phase transitions (RPTs), which cause fascinating phenomena in these multicomponent systems. Here, changes in temperature and/or addition of one of the components give rise to a recurrence of the original phase (11, 13, 14). This phenomenon was recently found to play a critical role in the formation of intracellular membraneless organelles, which are mainly systems based on liquid-liquid phase separation (15–17). A broader perspective on phase transitions in molecular systems with many components under thermodynamic equilibrium has been presented by Jacobs and Frenkel (18). Their statement—that only minor adjustments to the strengths of intermolecular interactions are required to regulate the formation of different domains with specific compositions—is relevant for our current study.

Two frequently used units to construct aqueous synthetic supramolecular systems are surfactants and supramolecular monomers (6, 19–24). Monomer BTA-EG4 undergoes supramolecular polymerization in water to afford one-dimensional aggregates at micromolar concentration driven by hydrogen bonding and hydrophobic effects, and is made water-soluble by hydrophilic tetraethylene glycol ethers showing fibers less than 500 nm in length. At 3 eq. of CTAB (Fig. 2C). This transition was determined by competitive supramolecular pathways in water. It is combined with the development of two integrated RPTs (gel-sol-gel-sol) upon dilution with the supramolecular units shown in Fig. 1. To elucidate the pathways that direct the sol-gel transition upon dilution, we investigated the interaction between BTA-EG4 and a library of surfactants at micromolar concentrations (figs. S10 to S16). We illustrate our detailed explorations using a combination of spectroscopic, cryo-TEM, light scattering, iso-thermal titration calorimetry, and theoretical techniques (Fig. 2 and figs. S1 to S5, S17 to S21). We observed a gradual increase in intensity and resolution of the peaks associated with BTA-EG4. At 2 eq. of CTAB, the ethylene glycol peak of BTA-EG4 appeared; 1H diffusion-ordered spectroscopy (DOSY) NMR (fig. S17) revealed that all the surfactants were still embedded, but in much smaller aggregates. These smaller aggregates were confirmed by cryo-TEM images showing fibers less than 500 nm in length. At 3 eq. of CTAB, both signals corresponding to BTA-EG4/CTAB micelles were observed in DOSY NMR; cryo-TEM showed small spherical aggregates and occasionally short fibers. Ultraviolet-visible (UV-vis) spectroscopy confirmed fiber disruption and the formation of smaller BTA aggregates (Fig. 2C). This transition was dependent on the overall concentration as well as the ratio of both components (Fig. 2D), with more surfactants needed at lower BTA concentrations. The saturation of the polymer with surfactants destabilized the structure and destroyed the fibers at high concentrations of surfactant, most probably as a result of electrostatic and/or geometric constraints in the structures formed (Fig. 2E).

Studies with other surfactants revealed three relevant conclusions: (i) The affinity between the surfactant and BTA-EG4 is determined by the length of the aliphatic chain of the surfactant, (ii) BTA-EG4 fibers are unstable below the CMC of the surfactants, and (iii) the transition is dependent on both the overall concentration and the ratio of the components.
From these results, we hypothesize that the sol-gel transition upon dilution is driven by the concentration-dependent complexation of surfactants to BTA-EG₄ polymers. To corroborate this hypothesis, we constructed a thermodynamic mass-balance model that describes competition among supramolecular polymerization, micellization, complexation of CTAB to the polymers, and polymer collapse (Figs. 2, E and F, figs. S1 to S5, and supplementary text). We subsequently studied the dilution-induced effect of a solution of BTA-EG₄ with 3 eq. of CTAB, in which only small aggregates exist. Upon dilution, peaks corresponding to both BTA-EG₄ and CTAB gradually broadened and weakened in NMR (Fig. 2G) while the characteristic peaks (211 and 227 nm) in UV-vis spectra related to fiber structure appeared (Fig. 2H), as corroborated by cryo-TEM (fig. S21). We hypothesize that CTAB is released when the overall concentration decreases, thereby enabling the elongation of the BTA fiber to eventually achieve micrometer-long structures. The dilution-induced supramolecular polymerization became faster upon adding more water (Fig. S20).

With an understanding of the mechanisms underlying the dilution-induced supramolecular polymerization in water, an integration of two RPTs was developed by introducing an additional orthogonal interaction through two different strategies (Fig. 1C). The first strategy uses the intrinsic property of a polymeric surfactant to lead to further aggregation at higher concentration, whereas the second strategy takes advantage of an orthogonal supramolecular double network with a different gelation concentration window.

The polymeric surfactant, octyl polyethylene glycol (OPEG, 2 kDa; Fig. 1A and figs. S22 and S23) was synthesized with a C₈-spacer. The interaction of OPEG with BTA-EG₄ at micromolar concentration was evaluated by UV-vis, NMR, and cryo-TEM, showing a behavior similar to that observed for CTAB (figs. S24 and S25). Interestingly, an optimized BTA-EG₄/OPEG molar ratio of 2:3 ([BTA-EG₄] = 35 mM) in Milli-Q (MQ)-H₂O gave rise to an opaque Gel 1 with a mesh size of ~10 to 20 nm as indicated by cryo-TEM (Fig. 3A) and SAXS (fig. S36). The densely packed network was composed of wormlike fibers of fused BTA-EG₄/OPEG micelles. Rheological experiments showed a storage modulus, \( G' \), of up to 2 kPa with a complex viscosity, \( \eta^* \), above 2 kPa-s, as well as a fast and near-complete self-healing behavior (Fig. 3C to E). When diluting this gel with water to [BTA-EG₄] = 35 mM, a solution was obtained after equilibrium, owing to the dissociation of the fused micelles as depicted by cryo-TEM and SAXS. In line with the morphology transition, \( \eta^* \) dropped to ~1 Pa-s. When this solution was further diluted to [BTA-EG₄] = 27 mM, which is below the CMC of OPEG (~42 mM; fig. S26), a transparent and dynamic Gel 2 was formed with \( G' \) of ~5 Pa and \( \eta^* \) of ~10 Pa-s. This gelation was triggered by the dissociation/release of OPEG from the BTA-EG₄/OPEG micellar complex, which enabled the elongation of the BTA fibers and led to the formation of the typical, entangled BTA-EG₄ fiber network. With further dilution to [BTA-EG₄] = 0.8 mM and still the same BTA-EG₄/OPEG molar ratio of 2:3, the hydrogel changed into a viscous solution showing \( \eta^* \) of ~0.4 Pa-s and micrometer-long individual fibers. A detailed characterization of this gel-sol-gel-sol system (cryo-TEM, SAXS, and rheology) is presented in figs. S27 to S36.

The good biocompatibility of BTA-EG₄ (27) provides further opportunity for application of this multicomponent system in more complex media. Phosphate-buffered saline and DMEM/F12 basal medium were used for the whole process, showing RPT behavior identical to that observed in MQ-H₂O (fig. S37). Additionally, when physiological temperature was applied, \( G' \) of Gel 1 became reduced by a factor of 8 (\( G' \sim 250 \) Pa), probably owing to a fastened dissociation of BTA-EG₄/OPEG micelles (fig. S38).

The second strategy relies on an orthogonal supramolecular network formed by water-soluble supramolecular polymers based on the uredopyrimidinone unit (UPy-EG₁₁, Fig. 1A), which is less dynamic than BTA-EG₄ polymers (28).
In water, UPy-EG11 gives rise to micrometer-long bundled fibers with a width of ~5 to 14 nm. UPy-EG11/CTAB interactions were confirmed by $^1$H NMR (fig. S89). However, UPy-EG11 and UPy-EG11/CTAB mixtures (up to 5 eq. of CTAB) showed almost identical UV spectra and cryo-TEM images, indicating that CTAB binds with UPy-EG11 bundles yet does not markedly disrupt the supramolecular polymer. When mixed, BTA-EG4 and UPy-EG11 form self-sorted homopolymers. Hence, BTA-EG4, UPy-EG11, and a surfactant make an ideal combination to construct an interpenetrating double network consisting of different gelation windows. As depicted in Fig. 3B, P to H, an opaque hydrogel Gel 1' was fabricated with a BTA-EG4:UPy-EG11:OTAB molar ratio of 3.2:1:21.2 at [BTA-EG4] of 93 mM in MQ-H2O. Gel 1' is mainly stabilized by the UPy-EG11 network, whereas BTA-EG4 exists as BTA-EG4/OTAB micelles. Upon dilution to [BTA-EG4] = 46.7 mM, the UPy-EG11 network was not dense enough to construct a three-dimensional network that tightly held all the water. As the length of the BTA-EG4 fibers was not sufficient to form a network because of interaction with the surfactant, a transparent solution with a low $n^*$ of ~1 Pa·s was accomplished. Further dilution yielded the sol-gel-sol transition as in the first strategy. All results of the detailed characterization are presented in figs. S40 to S43.

After exploring the different states at specific concentrations, we tested methods for tracking the formation of these polymers upon dilution. We used total internal reflection fluorescence microscopy (TIRFM) to trace the in situ formation of the supramolecular polymeric fibers after the addition of droplets of concentrated solution to an aqueous film (Fig. 4).
(See figs. S44 to S46 for details of the experimental setup.) When an aqueous droplet of [BTA][CTAB] (1:3, [BTA] = 250 mM), containing 5% BTA-Cy3 for visualization, was pipetted into the aqueous film and thus 100-fold diluted in situ, supramolecular fibers started to grow at several positions out of droplets (Fig. 4, A to C). The relatively slow process in thin films enabled us to follow the growth over time. Some of the fibers became many tens of micrometers long (Fig. 4A). In some cases, the fibers were connected to other droplets (Fig. 4C). In other cases, the fibers both grew and shrank, and the pulling of droplets by the contracting fibers could be observed (Fig. 4D and movies S1 to S4). We ascribe the growth and the shrinkage to concentration gradients from the droplet and against the droplet, respectively—a phenomenon similar to the dynamic interconnected networks formed by Marangoni flows in the mesoscale positioning of amphiphiles when extruded from the droplets (29). These results emphasize the critical role of concentrations in multicomponent systems and are useful to understand several phenomena in biology, where RPTs are critically important to understand cellular condensates.
Fig. 4. Kinetic in situ formation of fibers upon dilution. (A to C) TIRFM images from movies S1 and S2 upon addition of BTA-EG₄/CTAB droplets to a film of PBS over time. The droplets in time adhere to the surface and fibers are formed after several minutes, using 1% BTA-biotin. The green fluorescence is the result of 5% BTA-Cy3; the higher the intensity, the higher the concentration of BTA. The increase of the droplet size results from an increased adhesion of the droplet to the surface. The increase in length of the fibers is the result of dilution-induced self-assembly/polymerization by diffusion of aggregates from the densely packed droplet to the continuous water film. (D) Snapshots from movies S3 and S4 of the shrinkage (white arrow) and connection (yellow arrow) of the fibers due to concentration gradients. Scale bar, 5 μm.

Dilution-induced ordering
Many molecules, such as surfactants, can form ordered structures when placed in solution. Typically, the systems become more ordered and the structures change from spheres to elongated shapes as the concentration is increased. Su et al. studied a system of benzene-1,3,5-tricarboxamide (BTA-EG4) with the cationic surfactant octyltrimethylammonium bromide (OTAB), in water (see the Perspective by Webber). BTA-EG4 undergoes supramolecular polymerization in water and will form hydrogels at higher concentrations, whereas OTAB will form small aggregates. However, when combined, the OTAB initially disrupts the BTA-EG4 hydrogels, but these can be reestablished upon dilution because this lessens the effect of the surfactant. With careful engineering, this can be expanded to a gel-sol-gel-sol system as a function of concentration. —MSL
