ABSTRACT

The H₂-distributed feeding concept using Pd/Ag-based membranes and an Ru-based catalyst in a Packed Bed Membrane Reactor (H₂-PBMR) for the synthesis of biofuels via the so-called Fischer-Tropsch Synthesis has been demonstrated. The most successful approach resulted when H₂-poor syngas (H₂/CO = 1) typically obtained from the gasification of biomass was fed directly through the reaction chamber, i.e., to the catalyst bed, whereas the H₂ needed to reach the proper stoichiometry for the FTS (H₂/CO = 2) was admitted, and properly distributed, into the catalyst bed through the Pd/Ag-based membrane by flowing H₂/He mixtures at the retentate side of the membrane. Under the optimum reaction conditions, the CO conversion measured with the H₂-distributed feeding concept is lower than that obtained in a conventional Packed Bed Reactor with H₂/CO = 2 (37.9 vs 50.7%), but significantly higher than that obtained in a conventional reactor with H₂/CO = 1 (14.1%). Remarkably, the productivity towards high-molecular hydrocarbons increases by almost 70% and the methane production decreases by one order of magnitude when using the H₂-distributed feeding concept in a Packed Bed Membrane Reactor.

1. Introduction

The Fischer-Tropsch Synthesis (FTS) is a well-established technology for the production of synthetic fuels and chemicals from syngas obtained from natural gas or coal [1]. The overall process comprises the transformation of natural gas or coal into syngas, a mixture of H₂ and CO with different stoichiometries, depending on the source and reaction conditions, which is further transformed into hydrocarbons in the presence of a catalyst via the FTS. These processes are known as coal to liquids (CTL) or gas to liquid (GTL processes). In recent times, the possibility of obtaining syngas via biomass gasification has encouraged the interest in the FTS as a route for obtaining second-generation biofuels via the so-called BTL (biomass to liquid) process [2,3]. Industrial FTS plants are based on Fe- or Co-based catalysts producing mainly short olefins and gasoline or paraffinic waxes, respectively [4]. The scale of the CTL and

GTL plants is a key factor in the economy of the overall processes. In fact, in order to be competitive, modern GTL plants are very large. For instance, it is reported that Shell's Pearl GTL plant in Qatar has the capacity of producing up to 260,000 barrels of GTL products and natural gas liquids per day treating 1.6 billion cubic feet per day of gas. However, it is highly unlikely that biomass could supply syngas at similar high rates as natural gas. As a consequence, it is expected that the scale of BTL plants have to be significantly smaller than that of CTL or GTL plants. Thus, in order to be competitive, it is necessary to increase the per-pass production of HC from syngas by developing more efficient processes and improving the catalysts to produce the desired hydrocarbon fraction. It is well known that Ru-based catalysts exhibit remarkably higher intrinsic activities than Fe or Co catalysts [4]. Moreover, they can operate in the presence of high partial pressures of water (the main co-product of the FTS reaction) and other oxygenate-containing atmospheres that have triggered the interest in Ru-based catalysts for FTS [5–9].

The FTS results in the formation of a pool of heteroatom-free linear paraffinic hydrocarbons ranging from CH₄ to waxes of 50 plus carbon atoms. The high molecular weight hydrocarbons are reformed downstream into the desired product family, mostly diesel or jet fuel fractions. Hydrocarbon formation in the FT reaction

is very similar to polymerization kinetics in which hydrocarbons are formed by the addition of monomers of activated C₁ groups to the end of an absorbed growing hydrocarbon chain [10]. Due to this polymerization kinetics, there will always be a range of hydrocarbon products C₁₊ whose selectivity can be described by the Anderson, Schulz, Flory (ASF) distribution. The chain growth possibility, the α value (which ranges between 0 and 1) is commonly used to describe the product distribution of the FTS. The higher the α value, the higher the fraction of high molecular weight products.

The FTS product distribution can be controlled, at least to some extent, by the adequate use of the catalyst and reaction conditions (pressure, temperature, H₂/CO ratio and Gas Hourly Space Velocity, GHSV) [10]. The use of membrane reactors offers the possibility of increasing process intensification, while increasing the reaction conversion and the selectivity towards the desired product fraction. However, studies about catalytic membrane reactors for the FTS are scarce, especially experimental studies. Most of these studies are based on H₂O-separation membranes in order to shift the equilibrium (H₂ + CO \rightarrow -CH₂- + H₂O) to the formation of hydrocarbons. However, the results obtained show no benefits as compared to those reported in a Packed Bed Reactor (PBR), mostly because the membranes did not show sufficient selectivity for water removal under FTS conditions [11].

Membranes as reactant distributor along the reactor axis have been proposed to control the activity and product selectivity, since they depend significantly on the H₂/CO ratio. Thus, the concept of distributed feeding of H₂ can be used to enhance the selectivity to long-chain products, since the H₂/CO ratio remains constant along the reactor axis [12]. Leonard et al. [13,14] and Guillou et al. [15] presented a conceptual study on distributed feeding of H₂ along the reactor axis. The membrane was either inert (γ -Al₂O₃ on α -Al₂O₃) or coated with a ZSM-5 zeolite layer. The distribution of H₂ into a CO feed stream lead to low H₂/CO-ratios in the catalytic bed and as a consequence to lower conversions along with higher C₁₀₊ hydrocarbon yield and lower methane selectivity. In addition, low H₂/CO ratios could result in a higher formation of coke and/or high molecular weight hydrocarbons that remain adsorbed on the catalyst surface thus deactivating the catalyst. The application of the ZSM-5 membrane also altered the product distribution by secondary reactions at the acidic sites of the zeolite, resulting in higher yields of short-chain hydrocarbons. These results show a promising alternative to convert biomass-derived H₂-poor syngas into valuable hydrocarbons.

Recently, some works have modeled the use of membrane reactors for the FTS. Rahimpour et al. proposed a 1D heterogeneous model of the FTS reactor using Fe-based catalysts in which a fixed bed reactor is combined with a membrane-assisted fluidized bed reactor. The results obtained by the model showed an enhancement in the gasoline yield, a main decrease in CO₂ formation and a favorable temperature profile compared with a conventional fixed bed reactor [16].

More recently, Ghareghashi et al. [17] reported a simulation of the use of two consecutive reactors: a catalytic fixed bed reactor for the oxidative coupling of methane (OCM) and a fixed bed membrane FTS reactor using a Pd/Ag based H₂ perm-selective membrane and an Fe-based catalyst. The study concluded that the concept of a membrane FTS reactor together with OCM feed is an interesting method for increasing C₅₊ and decreasing undesired products such as CO₂ and methane.

In addition, Nouryzadeh et al. modeled the H₂ and gasoline production in a heat exchanger reactor [18] called Thermally Coupled Recuperative Reactor which is composed of two concentric tubular fixed bed reactors. In this interesting concept, the exothermic reaction (FTS) generates heat that is transferred to the endothermic side (outer side) where the dehydrogenation of cyclohexane to produce H₂ takes place. The H₂ produced is fed along the FTS reactor

through a Pd/Ag perm-selective membrane. According to the model results, this configuration offered some important improvements compared with the conventional FTS, thus increasing the gasoline yield.

In summary, some experimental results and especially some recent modeling studies indicate that the use of the so-called H₂-distributed feeding concept in FTS by using membrane reactors could have a beneficial effect enhancing the selectivity towards high molecular weight hydrocarbons while decreasing the selectivity to undesired methane and/or CO₂. Moreover, the use of Pd/Ag membranes have recently received great interest due to their unique properties for the separation of H₂, high permeability and selectivity to H₂ [19,20]. These improved properties could help to implement the use of H₂-distributed feeding concept in a membrane reactor applied to the FTS.

To the best of our knowledge, there are no experimental works about the use of the H₂-distributed feeding concept with membrane reactors for FTS using Pd/Ag membranes.

In this paper, we show the beneficial effect of using Pd/Ag membranes for H₂-distributed feeding in a Packed Bed Membrane Reactor (PBMR) compared to a conventional Packed Bed Reactor (PBR) for FTS with a Ru-based catalyst. H₂-poor syngas (H₂/CO = 1), which is the typical value of the syngas obtained by gasification of biomass [21], was fed to the reaction chamber (inner side of the membrane) and the H₂ needed to reach the desired FTS stoichiometry (H₂/CO = 2) was admitted (and properly distributed) into the reaction chamber through the Pd/Ag-based membrane resulting in an enhancement of the productivity of high molecular weight hydrocarbons. The experimental study is supported by model simulations.

2. Experimental

2.1. Preparation of the B-Ru/TiO₂ catalyst

B-doped Ru/TiO₂ (3 wt% Ru; B:Ru 1:1 at), RuB₁Ti was used as the FTS catalyst. The catalyst was prepared by sequential impregnation of TiO₂ (P25) with water solutions of RuNO(NO₃)₃ and HBO₃. A solution of the Ru precursor was added to TiO₂ by incipient wetness impregnation with a 0.09-M aqueous solution of Ru precursor and dried overnight. The solid recovered was calcined in static air at 450 °C (10 °C min⁻¹) for 3 h. The resulting solid (Ru/TiO₂) was impregnated with aqueous solution with the adequate amount of H₃BO₃ to obtain a B/Ru atomic ratio of 1, dried at room temperature and calcined again in static air at 450 °C (10 °C min⁻¹) for 3 h.

2.2. Catalyst characterization

X-ray diffractograms were collected on a Seifert 3000 powder diffractometer operating with Cu K α radiation ($\lambda = 0.15418 \text{ nm}$) generated at 40 kV and 40 mA. Scans were recorded at 0.02 °s⁻¹ for 2 θ values between 10° and 90°. H₂ temperature-programmed reduction (H₂-TPR) analysis of the catalyst was carried out with a Micromeritics instrument using a U-shaped quartz reactor. Prior to the reduction experiment, the catalyst was flushed with a He stream at 373 K for 30 min and then cooled down to room temperature. TPR profiles were obtained by heating the sample under a 10% H₂/Ar flow (50 mL min⁻¹) from 303 to 1173 K (10 K min⁻¹).

2.3. Preparation of Pd/Ag-supported membranes

A 15-cm long alumina tube with an outside pore size of 100 nm and 10/7 mm o.d./i.d. was used as membrane support (provided by Rauschert Kloster Veilsdorf), both ends were glazed leaving 60 mm of porous part in the middle of the membrane. A thin Pd-Ag layer ($\approx 4 \mu\text{m}$ thick and silver content of ~23–27%) was deposited on the

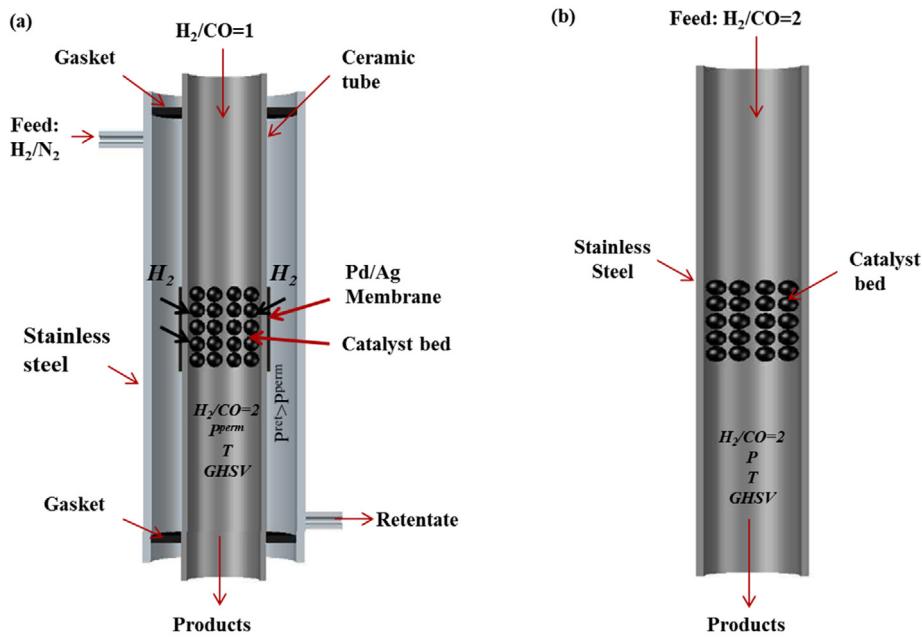

Fig. 1. (a) Scheme of the membrane reactor for H₂ distributed feeding (H₂-PBMR); (b) scheme of traditional PBR.

porous alumina tube first by simultaneous Pd and Ag electroless plating (containing 13–15% of Ag) [20] in order to increase the amount of Ag to avoid fragilization, more Ag was deposited by PVD magnetron sputtering (CemeCon CC800/8) using an Ag target with similar conditions of deposition as reported before [22]. After the deposition of the Ag layer, the membrane layer was annealed at 823 K for 4 h under a 10% H₂/90% N₂ gas mixture. Similar Pd–Ag membranes (\approx 3.2- μm thick and silver content of ~13–15%) showed a H₂ permeance of 0.0025 mol m^{−2} s^{−1} Pa^{−0.5} at 587 K when feeding pure H₂ [20].

2.4. Catalytic activity tests

Catalytic tests in a Packed Bed Reactor (PBR) and in a Packed Bed Membrane Reactor (PBMR) were conducted at temperatures of 523 and 553 K, P = 1.0 MPa and GHSV = 7500 mL_{syngas}/g_{cat}/h. In the PBMR configuration, the catalyst was placed inside of the alumina membrane assuring that its location coincides with that of the Pd–Ag layer. With this configuration, it would be expected that H₂ permeated from the outer layer of the membrane would only be distributed along the catalytic area in the reactor. Prior to the catalytic tests, the catalyst was activated *in situ* by flowing H₂ at 523 K for 60 min to ensure the formation of the active phase for the FTS. In the PBR, syngas (H₂/CO = 2) is fed to the catalytic chamber. However, in the PBMR, CO and H₂ are fed to the catalytic bed through the catalytic chamber (CO) and through the membrane side (H₂) so that the overall ratio H₂/CO = 2 is achieved. For this purpose, the H₂ permeation through the membrane was measured by flowing H₂ and CO through the retentate and the permeate sides of the membrane, respectively (see Fig. 1).

The analysis of the reaction products was done with an in-line GC equipped with FID and TCD detectors equipped with a cryogenic unit.

3. Modeling

3.1. Model description

A state-of-the-art pseudo-homogeneous 1D reactor model is employed for simulations of the multi-compartment packed bed

and packed bed membrane reactor. The model solves the mass and energy balances of all the compartments simultaneously. In the mass balances accumulation (left-hand side), convection, axial dispersion and heterogeneously catalyzed chemical reactions and a membrane source/sink term, respectively, on the right-hand side has been accounted for:

$$\frac{\partial \varepsilon_g \rho_g \omega_i}{\partial t} = -\frac{\partial \varepsilon_g \rho_g u_g \omega_i}{\partial z} + \frac{\partial}{\partial z} \left(\rho_g D_{ax} \frac{\partial \omega_i}{\partial z} \right) + n_i a_s + \varphi''_{m,i} a_m$$

The equations are solved using Danckwerts inlet boundary conditions and free-flow outlet conditions:

$$-\rho_g D_{ax} \rho_g \frac{\partial \omega_i}{\partial z} \Big|_{z=0} + \varepsilon_g \rho_g u_g \omega_i \Big|_{z=0} = \varphi''_{inlet,i} \quad \frac{\partial \omega_i}{\partial z} \Big|_{z=L} = 0$$

The energy balance is formulated in a similar fashion, with an additional term for heat exchange via the confining wall.

$$\begin{aligned} \varepsilon_g \rho_g C_{p,g} \frac{\partial T}{\partial t} &= -\varepsilon_g \rho_g C_{p,g} u_g \frac{\partial T}{\partial z} + \frac{\partial}{\partial z} \left(\lambda_{g,eff} \frac{\partial T}{\partial z} \right) + \sum_{i=1}^N n_i a_s H_i \\ &\quad + \sum_{i=1}^N \varphi''_{m,i} a_m H_i + a_{b \rightarrow w} a_w (T - T_\infty) \end{aligned}$$

with similar Danckwerts inlet and free-flow outlet conditions:

$$-\lambda_g \frac{\partial T}{\partial z} \Big|_{z=0} + \varepsilon_g \rho_g C_{p,g} u_g T \Big|_{z=0} = \sum_{i=1}^N H_i \varphi''_{inlet,i} \quad \frac{\partial T}{\partial z} \Big|_{z=L} = 0$$

Mass conservation was enforced via the total continuity equation:

$$\varepsilon_g \frac{\partial \rho_g}{\partial t} = -\frac{\partial \rho_g u_g}{\partial z} - \phi''_{m,tot} a_m \text{ with } a_m = \frac{4d_i}{d_o^2 - d_i^2}$$

where, d_o and d_i represent the outer and inner diameter, respectively, while the pressure drop over the catalyst bed was computed using the differential Ergun equation.

The multi-compartment layout is used to describe the different parts of the Packed Bed Membrane Reactor (PBMR), *i.e.*, the reactor tube (compartment 1) and the membrane tube (compartment

Table 1

Experimentally determined membrane parameters for the used Pd/Ag membrane, which were set in the numerical model.

| Parameter | Value | Unit |
|---------------------|------------------------|--|
| $Q_{\text{Pd},0}$ | 6.135×10^{-8} | $\text{mol m}^{-1} \text{s}^{-1} \text{Pa}^{-n}$ |
| $E_{\text{act,Pd}}$ | 7.799 | kJ mol^{-1} |
| δ | 4.8×10^{-6} | M |
| n | 0.5 | |

2). Exchange of hydrogen between the two compartments via the Pd–Ag perm-selective membrane is described with Sieverts' law:

$$J_{\text{H}_2} = \frac{Q_{\text{Pd}}}{\delta} (p_{\text{H}_2, \text{tube}}^n - p_{\text{H}_2, \text{shell}}^n) \text{ with } Q_{\text{Pd}} = Q_{\text{Pd},0} \exp\left(-\frac{E_{\text{act,Pd}}}{RT}\right)$$

where, the parameters were fitted to permeance data obtained from dedicated experiments (see Table 1).

The FTS reaction kinetics have been based on the reaction scheme proposed by Visconti et al. [23–25] for Co-based catalysts (listed in Table 2), but with modified kinetic parameters for the Ru-based catalyst used in this work.

The reaction rate constant in reaction 1 and 2a is modeled using a modified Arrhenius equation:

$$k = k_0 \exp\left[-\frac{E_a}{R} \left(\frac{1}{T} - \frac{1}{503}\right)\right]$$

The implementation of the kinetic scheme was verified by comparing simulations to results published in the works by Visconti and coworkers, which gave satisfactory results. The Ru-B/TiO₂-based catalyst was modeled by changing the kinetic rate parameters and activation energies, so that simulation results would closely match the experimental kinetic results. This fitting procedure was performed by manually fitting the most important kinetic rate parameters to match experimental and simulated conversion and selectivities using a base case of $P=20\text{ bar}$, $T=523\text{ K}$, $\text{GHSV}=10,000\text{ mL/g}_{\text{cat}}/\text{h}$ and a H₂/CO ratio of 2. Comparison with experiments at different temperatures indicated a required change in the activation energies of kinetic rate equations 1 and 2a (Table 2). Table 3 gives the newly fitted parameters for the Ru-B/TiO₂-based catalyst, along with those provided by Visconti [23] for their Co-based catalyst. Table 4 shows the results of a comparison of the quality of the fit between the Ru-B/TiO₂ experiments and simulations.

Table 2

Elementary reactions and kinetic rate expressions for FTS on Co-based catalysts, as used in the numerical model reported in [23]. Here, P and Q indicate generic linear paraffin and olefins, respectively, and θ indicates the fraction of free catalytic sites, while * indicates a single free catalytic site.

4. Results

4.1. Catalyst characterization

Fig. 2a shows the X-ray diffractograms of the B-Ru/TiO₂ catalyst. The diffractogram of the TiO₂ is shown for comparison. As observed, both diffractograms show identical diffraction lines characteristic for the rutile and anatase phases of TiO₂. Diffraction lines indicative of Ru or B phases are not observed, indicating that Ru is well dispersed onto the TiO₂ support. Fig. 2b shows the H₂ consumption profile vs temperature for B-Ru/TiO₂. A single peak centered at ca. 450 K is observed indicating a good dispersion of the Ru particles onto TiO₂.

4.2. Pd/Ag membranes: effect of CO on H₂ flux permeated

Prior to the FTS tests in the PBMR configuration, the H₂ flux through the membrane and the effect of the presence of CO on the H₂ permeation through the Pd/Ag membranes was studied. To conduct these experiments, the volume of inert material (SiC) sufficient

to fill the length of the membrane was placed inside the membrane and the temperature of reactor was raised to 553 K under He flow (170 mL min⁻¹). Once this temperature was reached, the He total pressure at the outer side of the membrane was set between 0.1 and 0.3 MPa, while the inner side of the membrane was maintained at atmospheric pressure. The He flux permeated through the Pd/Ag membrane (or sealing) was less than 2% of the total He flow within the entire pressure range under study. In a following step, the H₂ permeation was measured at 553 K using 103 mL min⁻¹ of H₂ and a constant flow rate of 75.6 mL min⁻¹ of He at 0.1 MPa at the inner part of the membrane. In order to study the effect of CO on the H₂ permeation rate, the experiments were also conducted by flowing CO/N₂ (80/20) 75.6 mL min⁻¹ instead of He at the inner part of the membrane. The H₂ pressure at the outer side of the membrane ranged between 0.1 and 0.3 MPa in all cases. The results are shown in Fig. 3. The difference of H₂ partial pressure was calculated by assuming that the H₂ pressure inside the membrane was zero.

The results shown in Fig. 3 clearly indicate that the permeability of the Pd/Ag membrane decreases when CO is fed through the inner side of the membrane. This is caused by the stronger adsorption of CO compared to H₂ onto the Pd atoms, thus decreasing the H₂ permeation. However, this poisoning effect is not complete, and the presence of CO does not lead to complete deactivation of the membrane permeation at the temperatures and pressures used in this study, and still a quite high H₂ permeation is observed even with a CO/N₂ flux at the inner side of the membrane. Thus, it can be concluded that it is possible to obtain sufficient H₂ permeation under FTS conditions by using Pd/Ag membranes.

4.3. FTS activity tests: PBMR vs PBR

Pd membranes are typically designed to work at temperatures above 573 K, whilst the reaction of Fischer-Tropsch with a Ru-based catalyst like the one used in this work is usually carried out at temperatures between 488 K and 523 K. At these low temperatures, Pd membranes suffer from the so-called “embrittlement” effect, which

is a metal degradation process due to the coexistence of the hydrides H₂-Pd (α - β) in the membrane [26]. Pd/Ag membranes are more resistant to embrittlement; however, due to the high pressure of H₂ in the reaction and higher H₂ permeation at higher temperatures, temperatures above 523 K were selected. As a consequence, it can be anticipated that a mismatch between the optimum reaction conditions for the FTS and the optimum working conditions of the membranes exists that could limit the implementation of PBMR for FTS. Therefore, operation conditions must be chosen as a compromise between the optimal ones for the FTS and for H₂ permeation, or further optimization of the catalyst and/or membrane needs to be pursued.

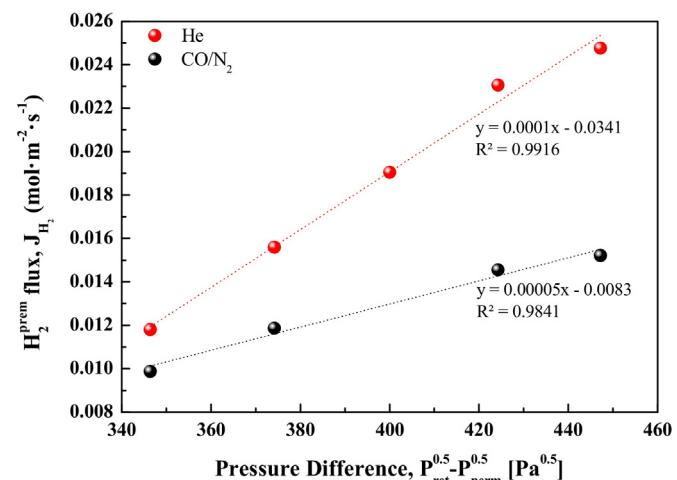

Fig. 3. H₂ flux of Pd/Ag membrane at 553 K (H₂ fed 103.2 mL_N/min) vs pressure difference feeding He (red) and CO/N₂ (black) inside the membrane. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

In a first approach, the H₂-PBMR FTS tests were conducted at 523 K with a feed composition of H₂/CO/N₂ = 46/46/8 to the inner compartment. Note that the H₂/CO ratio is equal to 1, similar to the one obtained from biomass gasification, but lower than the stoichiometric H₂/CO ratio for the FTS. To compensate the lack of H₂ (with respect to the stoichiometric FTS value), H₂ is permeated homogeneously through the outer side of the membrane (along the whole length of the membrane) by flowing a mixture of H₂/He to the outer side of the membrane. In this approach, the membrane is used to supply (and to distribute H₂ homogeneously throughout the entire length of the membrane, *i.e.*, through the catalyst bed) the extra H₂ needed to achieve the stoichiometric H₂/CO ratio into the FTS reaction chamber ensuring a proper distribution of the H₂ through the entire catalyst bed. The pressure in the permeate chamber was set at 1.0 MPa (46/46/8 of H₂/CO/N₂). In order to create a driving force to allow H₂ to permeate through the membrane into the reaction zone, an H₂ partial pressure difference of 0.44 MPa was set ($\Delta P^i_{H_2} = P_{H_2}^{ret} - P_{H_2}^{perm} = 0.44$ MPa) by adjusting the pressure of the outer chamber to 1.2 MPa (H₂/He = 75/25). In order to obtain the desired H₂/CO ratio of 2 in the catalyst bed during the FTS at the selected GHSV, the H₂ flux permeated to the reaction zone was calculated previous to each FTS reaction. The permeated H₂ flux was calculated by subtracting the H₂ flow feed at the inlet of the membrane side from the non-permeated H₂ flow measured at the retentate side at the outlet of the reactor. Thus, in the reaction zone, a syngas with an H₂/CO ratio of 2 at 7500 mL_{H₂+CO}/g_{cat}/h is set.

Fig. 4a shows the evolution of the CO conversion with time-on-stream (TOS) obtained at 553 K using the H₂-PBMR FTS concept using the Pd/Ag membrane. For reference, the results obtained with a conventional FTS-PBR measured under similar reaction conditions, *i.e.*, 553 K, 1.0 MPa, 7500 mL_{syngas}/h/g_{cat} and H₂/CO ratios of 1 and 2 are also shown.

Noticeably, the H₂-distributed PBMR concept using H₂-poor syngas at the inner side of the membrane, (H₂/CO = 1) and supplying extra H₂ from the outer side of the membrane, renders similar initial CO conversion values compared to those obtained with the traditional FTS PBR with H₂/CO = 2 and significantly higher than those with a PBR using a H₂-poor syngas (H₂/CO = 1). As shown in **Fig. 4b**, the initial selectivity towards the different products is significantly influenced by the presence of the membrane. Thus, the production of C₁ decreased from *ca.* 22% in the traditional PBR (H₂/CO = 2) to 5.7% in the PBMR. The selectivity towards light hydrocarbons remains similar but the production of long-chain hydrocarbons, C₅–₁₀ and C₁₀₊ fractions increases noticeably in the PBMR, especially the latter which increases from *ca.* 15.6% to 49.4%. **Fig. 4b** also shows the results of numerical simulation results of the comparison of the PBR with the PBMR concept. The numerical model describes qualitatively the same results, showing a decreased CH₄ production and increased C₅₊ production when using the membrane reactor concept, although to a lesser extent. Discrepancies may come forth due to the fact that the simulation results were taken from steady-state operation, and the kinetic model for the catalyst requires further fine tuning (*i.e.*, automated fitting based on larger data sets) in order to change qualitative agreement into quantitative agreement.

However, after a few hours on stream, the CO conversion recorded using the H₂-PBMR drops to levels comparable to the ones recorded with the traditional PBR fed with a syngas with H₂/CO = 1. Alongside with the decrease in the CO conversion, we observed a reduction of the H₂ permeation rate through the membrane. Such an effect could be due to membrane deactivation by adsorbed CO species and/or blocking of membrane pores by adsorption of waxes formed during the FTS. Both these effects could explain the observed decrease in the H₂ permeation rate through the membrane resulting in a H₂-poor syngas within the FTS reaction chamber and consequently to a decrease in the CO conversion level.

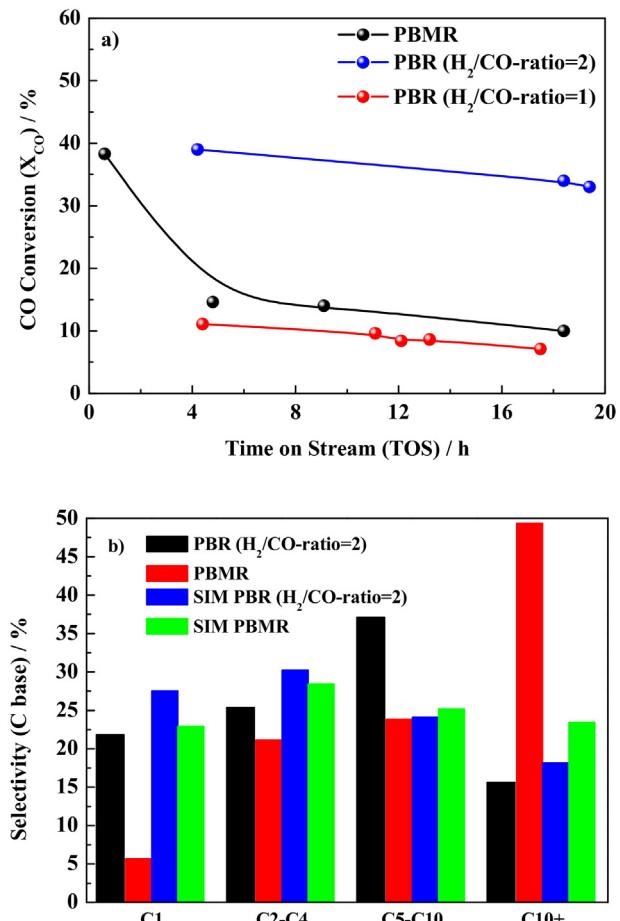

Fig. 4. (a) CO conversion at 523 K vs TOS in H₂-PBMR (H₂/CO = 1)_{perm} (black) and in a conventional FTS PBR with H₂/CO = 2 (blue) and H₂/CO = 1 (red). P = 1.0 MPa, GHSV = 7500 mL_{CO+H₂}/g_{cat}/h and $\Delta P^i_{H_2} = 0.35$ MPa. (b) Product selectivity for PBR H₂/CO = 2 (black) and PBMR (red) during the first hours of reaction, compared to model results (blue and green). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

In addition, it may cause catalyst deactivation due to the formation of coke. **Fig. 4a** shows that after *ca.* 10 h on stream the H₂-PBMR behaves as a conventional PBR fed with H₂-poor syngas (H₂/CO = 1). Similar CO conversion levels of around 10% and 15% are recorded for both configurations suggesting that H₂-poor syngas is responsible for the decreasing CO conversion recorded using H₂-PBMR. The slightly higher CO conversion obtained with the H₂-PBMR could indicate that a fraction of H₂ is still permeating through the membrane, but not enough to maintain the FTS stoichiometric syngas ratio H₂/CO of 2.

Fig. 5 shows a picture of the inner side of the membrane tube recovered after the FTS reaction in the H₂-PBMR. The image clearly shows the presence of waxes in the inner side of the tube (in the catalytic zone), which probably result in the blocking of tube's pores, thus impeding H₂ permeation to the reaction chamber.

As shown above, Pd/Ag membranes are capable of supplying extra H₂ to the FTS reaction zone, so that the H₂/CO ratio can be adjusted to the desired stoichiometric FTS ratio. By doing that, CO conversions obtained in a H₂-PBMR and in a traditional packed bed reactor are similar. This behavior, however, is not a significant advantage of the use of the PBMR over the traditional PBR for FTS. However, as also shown in **Fig. 4b**, conducting the FTS in a H₂-PBMR results in a higher fraction of high molecular weight hydrocarbons and lower methane production than with a conventional PBR with H₂/CO = 2. **Fig. 4b** compares the products selectivity at the early

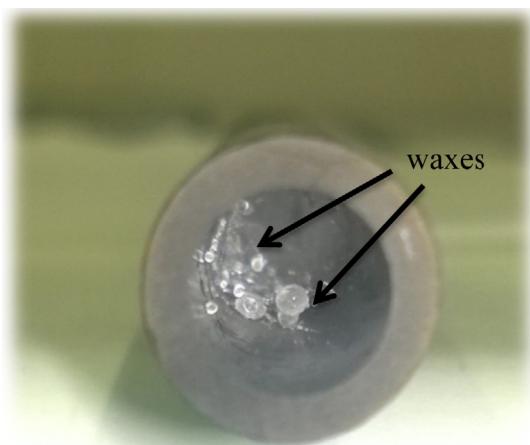

Fig. 5. Image of the H_2 -perm membrane recovered after the FTS synthesis. The presence of high molecular hydrocarbons (waxes) in the inner side of the membrane (the catalytic zone) is shown.

stages of the FTS ($\text{TOS} < 5 \text{ h}$), i.e., before membrane deactivation occurred. As observed, the production of high molecular weight hydrocarbons increased by a factor of 3 (ca. three times higher) and the production of methane is lower in the H_2 -PBMR than in the PBR. Both positive effects are probably related to an intrinsic property of the Ag/Pd membranes, which is the homogeneous distribution of H_2 along the entire length of the membrane. As a consequence, the H_2/CO ratio within the whole catalytic bed length is better controlled and remains constant in the entire catalyst bed so that areas with local concentrations of H_2 higher (which favor the production of methane) or lower (which favor the production of low molecular weight hydrocarbons) than the stoichiometric FTS value ($\text{H}_2/\text{CO} = 2$), prevailing in the conventional PBR, are circumvented.

With the aim to minimize the observed decrease in the H_2 permeation rate through the Pd/Ag membrane, FTS experiments were conducted at higher temperatures (553 K). Otherwise, the same reaction conditions were used. Feed flow rates were adjusted to reach the same $\text{GHSV} = 7500 \text{ mL}_{\text{CO}+\text{H}_2}/\text{g}_{\text{cat}}/\text{h}$. Syngas with a $\text{H}_2/\text{CO} = 1$ ratio was directly fed into the reaction side of the H_2 -PBMR, while extra H_2 to achieve an overall $\text{H}_2/\text{CO} = 2$ was supplied via the membrane. In the PBR, syngas with H_2/CO ratios of 1 and 2 was used. Fig. 6a displays the evolution of the CO conversion with time-on-stream (TOS) obtained at 553 K with the H_2 -PBMR and the conventional PBR reactor. Fig. 6b shows the selectivity towards the different fractions of hydrocarbons at initial TOS ($T < 5 \text{ h}$).

As clearly observed in Fig. 6a, increasing the reaction temperature to 553 K results in higher CO conversions than at 523 K (see Fig. 4) in all configurations under study. The CO conversion recorded with the H_2 -PBMR is higher than that measured in the PBR with $\text{H}_2/\text{CO} = 1$, but lower than that recorded with a PBR with $\text{H}_2/\text{CO} = 2$. This trend is similar to the one reported for the FTS experiments recorded at 523 K (see above). However, conducting the FTS at 553 K prevents the strong deactivation observed at 523 K, resulting in more stable CO conversion levels during time-on-stream in the H_2 -PBMR than at 523 K (see Fig. 4a). Two different yet complementary effects can justify the positive effect of the increasing reaction temperature. On the one hand, by increasing temperature the hydrogen permeance through the membrane increases. This feature results in a lower production of high molecular weight hydrocarbons and hence to a lower membrane deactivation. On the other hand, it is well known that the production of low molecular weight hydrocarbons increases with the increasing temperature. Combined, these effects lead to a lower production of high molecular weight hydrocarbons at 553 K than at 523 K as observed from

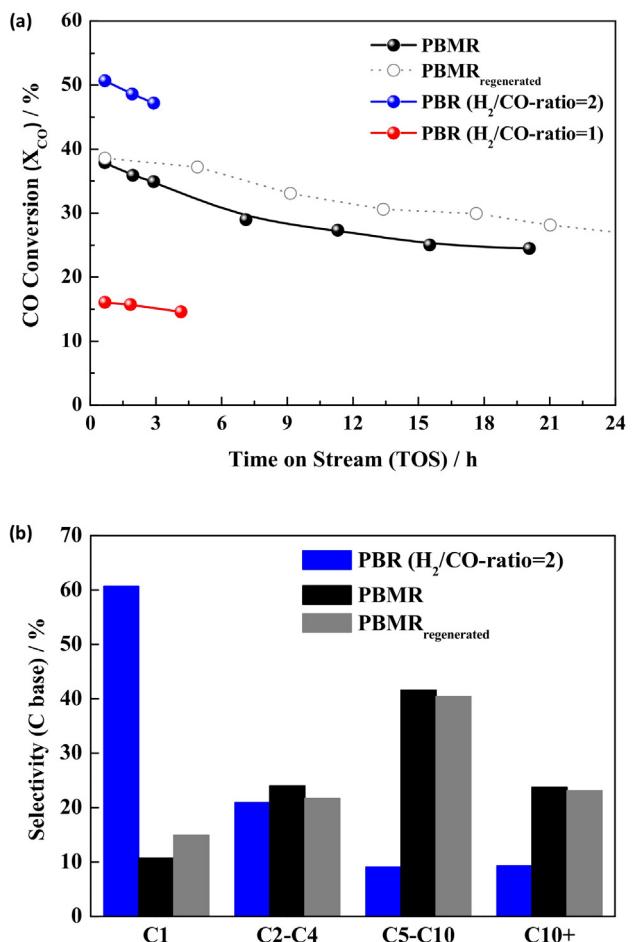

Fig. 6. (a) CO conversion at 553 K vs time on stream with catalyst RuB1Ti in PBMR ($\text{H}_2/\text{CO} = 1$)_{perm} (black color) and regenerated (open circles), PBR with $\text{H}_2/\text{CO} = 2$ (blue color) and $\text{H}_2/\text{CO} = 1$ (red color), $P = 1 \text{ MPa}$, $\text{GHSV} = 7500 \text{ mL}_{\text{CO}+\text{H}_2}/\text{g}_{\text{cat}}/\text{h}$ and $\Delta P_{\text{H}_2} = 0.35 \text{ MPa}$. (b) Product selectivity for PBR $\text{H}_2/\text{CO} = 2$ (blue bars), PBMR (black bars) and PBMR after thermal regeneration (green bars) during the first hours of reaction. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

Fig. 4b and Fig. 6b, and as a consequence of a lower membrane deactivation. This performance suggests that H_2 permeation can be successfully maintained during the course of the experiment.

Although increasing the reaction temperature leads to higher CO conversions, the production of high molecular weight hydrocarbons decreases, while that of CH_4 , an undesired product of the CTL and GTL processes, increases. For instance, CH_4 selectivity values of ca. 22% and 61% are recorded with the PBR ($\text{H}_2/\text{CO} = 2$) at 523 and 553 K, respectively. Although the impact of producing CH_4 during the BTL process may not be as detrimental as in the CTL or GTL processes, the CH_4 production at 553 K is still too high. However, and in line with the results obtained at 523 K, the experiments conducted at 553 K with the H_2 -PBMR led to a significantly lower production of methane (C_1 selectivity ca. 11%) as compared to that obtained in the PBR configuration (C_1 selectivity ca. 61%) along with an increase of the selectivity towards high molecular weight hydrocarbons (C_{10}^+) of about 2.5 times; see Fig. 6b. This effect is remarkable and it compensates for the consequences of conducting the FTS at temperatures as high as 553 K, opening new promising possibilities for the use of H_2 -PBMR for FTS.

Although to a lesser extent than when conducted at 523 K, a certain decrease in the CO conversion with TOS was also observed at 553 K. As shown above, this effect could be related to the formation of waxes in the inner side of the membrane that could

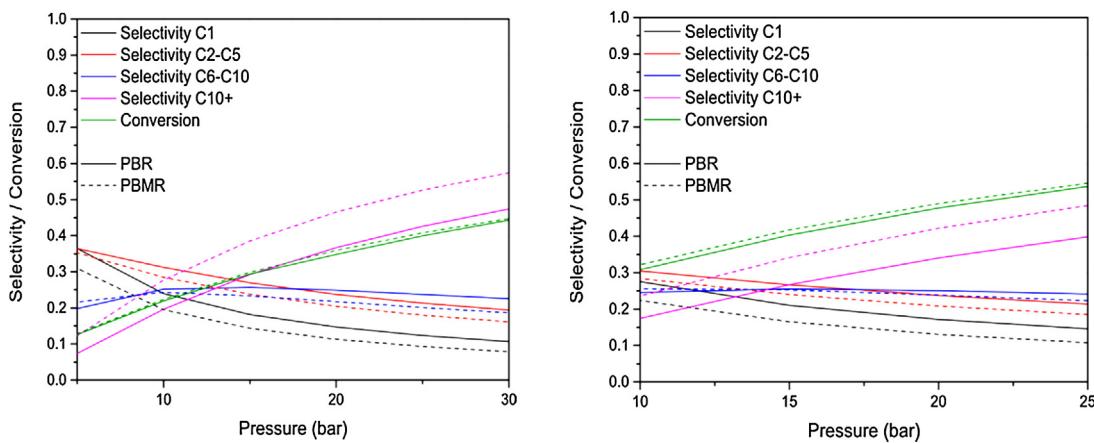

Fig. 7. Selectivities and CO conversion as a function of operating pressure with $\text{GHSV} = 10,000 \text{ mL}_{\text{CO}+\text{H}_2}/\text{g}_{\text{cat}}/\text{h}$ with catalyst RuB/Ti. (a) 523 K and (b) 553 K (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

Table 5

CO conversion and productivity using catalyst RuB1Ti in PBMR and PBR (syngas H_2/CO ratio: 1–2) at 553 K, $P = 1 \text{ MPa}$ and $\text{GHSV} = 7500 \text{ mL}_{\text{CO}+\text{H}_2}/\text{g}_{\text{cat}}/\text{h}$.

| FTS concept | $X_{\text{CO}} (\%)$ | $\text{g}_{\text{C}_5+}/\text{g}_{\text{cat}}/\text{h}$ | $\text{g}_{\text{CH}_4}/\text{g}_{\text{cat}}/\text{h}$ |
|----------------------------|----------------------|---|---|
| H ₂ -PBMR | 37.9 | 0.39 | 0.056 |
| PBR H ₂ /CO = 2 | 50.7 | 0.23 | 0.450 |
| PBR H ₂ /CO = 1 | 14.1 | 0.17 | 0.086 |

prevent H_2 permeation to the reactor side. In order to regenerate the membrane, the reaction was stopped after 20 h on stream and the membrane was subjected to an *in situ* heat treatment at 573 K under a flow of H_2 diluted in He (15%) in the outer side of membrane at and flowing pure He through the inner compartment of the membrane for 12 h. The regeneration was successful and the system recovered the same (or even higher) FT activity level (CO conversions) obtained during the first FTS test (see Fig. 6a) and the same selectivity towards the different fraction of hydrocarbons (see Fig. 6b).

Table 5 summarizes the CO conversion and productivity towards selected product families obtained with the H_2 -distributed PBMR concept with the Pd/Ag membranes using $\text{H}_2/\text{CO} = 1$ at the inner part of the reactor compared to the ones obtained with a traditional FTS PBR with $\text{H}_2/\text{CO} = 1$ or $\text{H}_2/\text{CO} = 2$.

As observed in Table 5, the conversion of CO with the H_2 -PBMR is lower than that obtained in the fixed bed reactor with stoichiometric syngas ($\text{H}_2/\text{CO} = 2$). However, by distributing H_2 through the membrane, a higher production of high molecular weight hydrocarbons (C_{5+}) and a significant decrease in CH_4 production (of *ca.* one order of magnitude) are observed. These results demonstrate for the first time experimentally that the use of membrane reactors with a distributed H_2 feed via Pd/Ag membranes can increase the production of the desired fraction of high molecular weight hydrocarbons provided that suitable FTS reaction conditions are identified. In addition, the results obtained confirm the predictions of recent models developed to study the use of different configurations of membrane reactors for FTS which predict the formation of a higher yield to heavier hydrocarbons fraction [16–18].

4.4. Numerical parameter study

The numerical model was used to further study the effect of the pressure and temperature on the selectivity towards different fractions using the packed bed reactor and Packed Bed Membrane Reactor concepts. The trend of conversion and selectivities for different fractions as a function of the pressure is shown in Fig. 7. It

is clear that for all cases, the membrane reactor concept is more selective towards long-chain components.

5. Conclusions

Despite the current mismatch between optimum temperature reaction conditions for the FTS and optimum temperature working conditions of the Pd/Ag membrane, this work has demonstrated experimentally the valuable use of the H_2 -distributed feeding concept for the FTS using a PBMR. The best conditions found for the H_2 -PBMR for FTS imply using a $\text{H}_2/\text{CO} = 1$ inside the reactor while supplying extra H_2 (to reach an overall $\text{H}_2/\text{CO} = 2$) via the membrane and a temperature of 553 K. The CO conversion recorded with the H_2 -distributed feeding PBMR concept for FTS with ($\text{H}_2/\text{CO} = 1$) is lower than that obtained in a conventional PBR feed with $\text{H}_2/\text{CO} = 2$ but the selectivity towards the targeted high-molecular hydrocarbons by H_2 -distribution in the PBMR increases by a factor of 3.

In addition, the newly synthesized catalyst Ru-B/Ti was modeled according to conventional kinetic models based on a Co-based catalyst with updated kinetic rate parameters. The kinetic model was built into a numerical reactor model which confirms the experimental results of a decreased CH_4 and increased C_{5+} selectivity.
