ABSTRACT

Guggenheim proposed a theoretical expression for the combinatorial entropy of mixing of unequal sized and linear and branched molecules to improve the Flory-Huggins model. Later the combinatorial activity coefficient equation, which was derived from Guggenheim’s model, was applied in the UNIQUAC, UNIFAC, and COSMOSAC models. Here we derive from Guggenheim’s entropy theory a new function for the number of nearest neighbors of a compound in a multicomponent mixture for which the knowledge of the coordination number and a reference area are not needed. This new relation requires only the mole, volume and surface fraction of the compounds in the mixture. The benefit of the new relation is that both the combinatorial and the residual term in the aforementioned models can be made lattice-independent. We demonstrate that the proposed relation simplifies the Staverman-Guggenheim combinatorial model and can be applied with success to the UNIQUAC and COSMOSPACE model in the description of vapor-liquid phase equilibria and excess enthalpy. We also show that the new expression for the number of nearest neighbors should replace the relative surface area and the number of surface patches in the residual part of the UNIQUAC and the COSMOSPACE model, respectively. As a result a more rigorous version of the UNIQUAC and the COSMOSPACE model is obtained. This could serve as a better basis for predictive models like UNIFAC, COSMO-RS and COSMOSAC.

1. Introduction

In the 1940s Huggins [1] and Flory [2] derived an expression for the combinatorial entropy of mixing of athermal mixtures consisting of unequally sized molecules. Guggenheim [3,4] showed that the FH model overestimates the combinatorial entropy of mixing, because the connectivity of sites in a molecule reduces the number of possible configurations. Consequently, Guggenheim derived a correction term on the Flory-Huggins (FH) model for molecules having no internal contacts, which can be linear or branched. Staverman [5] extended Guggenheim’s entropy expression to more complicated molecules, i.e. molecules containing rings. Both theoretical models contain, besides the mole and volume fraction, the surface fraction and require as additional parameter the number of nearest neighbors for each compounds. Abrams and Prausnitz [6] and Magnussen et al. [7] derived from the Staverman-Guggenheim (SG) entropy expressions for the activity coefficient, which have been applied in the combinatorial term of the UNIQUAC [6], DISQUAC [8], UNIFAC [9,10], COSMOSAC [11], COSMOSPACE [12] and MOQUAC [13] models. In this paper we show that from the Guggenheim entropy of mixing an alternative expression for the combinatorial activity coefficient equation can be obtained, and thereby a new formula for the number of nearest neighbors. With this new equation for the number of nearest neighbors we revise the 5G-corrected combinatorial activity coefficient as well as the residual activity coefficient of the UNIQUAC and the COSMOSPACE models. It makes the total activity coefficient, which is defined by the product of the combinatorial and the residual terms, for the UNIQUAC and COSMOSPACE model consistent. The new expression for the combinatorial activity coefficient equation is compared to the original form used in UNIQUAC and COSMOSPACE. In this comparison we will also consider the effect of the molecular size and shape defined by the Pauling bond lengths and the set of van der Waals radii, defined by Rowland and Taylor [14], respectively. Subsequently, the revised UNIQUAC and COSMOSPACE models are evaluated by comparing the description of vapor-liquid phase equilibria and excess enthalpy for alkane-alcohol binary systems.
2. Theory

2.1. Guggenheim’s entropy and the combinatorial activity coefficient

The mixing entropy $\Delta S$ for a binary mixture, consisting of molecules A and B, follows from Guggenheim’s model [3] as

$$\frac{\Delta S}{k_B} = \left(1 - \frac{z}{2}\right) \ln \left(\frac{r_A N_A}{(r_B N_B)}!\right) + \frac{z}{2} \ln \left(\frac{(q A N_A)!}{(q B N_B)!}\right) + \frac{1}{2} \ln \left(\frac{(q A N_A)!}{(q B N_B)!}\right)$$

(1)

Here $N_j$, $r_j$, $q_j$ are the number, the relative volume and the relative area of molecules $j$ in the mixture, $z$ is the lattice coordination number and $k_B$ Boltzmann’s constant. For a multicomponent system, where $M$ is the number of species, and applying Stirling’s approximation, the equation of Guggenheim becomes

$$\frac{\Delta S}{k_B} = \left(1 - \frac{z}{2}\right) \ln \left(\sum_{j=1}^{M} r_j N_j \ln(\phi_j)\right) + \frac{z}{2} \ln \left(\sum_{j=1}^{M} q_j N_j \ln(\theta_j)\right).$$

(2)

where $\phi_j$ and $\theta_j$ are defined as the volume and area fraction of molecule $j$ in the mixture

$$\phi_j = \frac{x_j}{\sum_{j} x_j r_j},$$

(3)

$$\theta_j = \frac{x_j q_j}{\sum_{j} x_j q_j},$$

(4)

and where $x_j$ is the mole fraction of component $j$. These expressions contain the relative van der Waals volume, $r_j$, and area, $q_j$, which require an ad-hoc definition of a reference volume and area. We recommend to use the van der Waals volume and area of the molecule, which can be calculated from molecular data as we will demonstrate in the results section, because the reference volume and area cancel in these equations. Further, it would be better to use the quantity $z q_j$ instead of $q_j$ in the expression of the area fraction, but since it is usually assumed that the lattice coordination number is the same for all molecules, it cancels in Eq. (4). Guggenheim introduced for the number of nearest neighbors of linear or branched molecules the formula

$$z q_j = z r_j - 2(r_j - 1).$$

(5)

This can be rearranged to:

$$\left(1 - \frac{z}{2}\right) r_j = 1 - \frac{z}{2} \theta_j.$$  

(6)

Upon substituting Eq. (6) into Eq. (2) Guggenheim obtained:

$$\frac{\Delta S}{k_B} = \sum_{j=1}^{M} N_j \ln(\phi_j) + \frac{z}{2} \ln \left(\sum_{j=1}^{M} q_j N_j \ln(\theta_j)\right).$$

(7)

To express the activity coefficient of compound $k$ in a mixture, we subtract first the ideal entropy of mixing to obtain the excess entropy

$$\frac{\Delta S^E}{k_B} = \sum_{j=1}^{M} N_j \ln(\phi_j) - \frac{z}{2} \ln \left(\sum_{j=1}^{M} q_j N_j \ln(\theta_j)\right).$$

(8)

and subsequently apply the thermodynamic relation

$$\ln \gamma_k^{\text{comb}} = \frac{\partial S^E_k}{\partial x_k}.$$  

(9)

This yields [7]:

$$\ln \left(\gamma_k^{\text{comb}}\right) = \ln \left(\frac{\phi_k}{x_k}\right) + 1 - \frac{\phi_k}{x_k} - \frac{z q_k}{2} \ln \left(\frac{\phi_k}{x_k}\right) + 1 - \frac{\phi_k}{x_k}.$$  

(10)

We recognize as first term the Flory-Huggins contribution and as second term the Staverman-Guggenheim correction [15,16]. Staverman [5] argued that Guggenheim’s entropy equation (Eq. (7)) is not valid for more complicated molecules, such as for molecules containing one or more rings. Vera et al. [17] demonstrated, however, that Eq. (10) is still obtained for bulky molecules. In the derivation above the $\left(1 - \frac{z}{2}\right) r_j$ term was replaced by the $\left(1 - \frac{z}{2}\right) q_j$ term in Eq. (2), but we can also replace the $\frac{z q_j}{2}$ term by $r_j \left(\frac{z}{2} - 1\right) + 1$. This gives

$$\frac{\Delta S^E}{k_B} = \sum_{j=1}^{M} N_j \ln \left(\frac{\theta_j}{x_j}\right) + \left(1 - \frac{z}{2}\right) \ln \left(\sum_{j=1}^{M} r_j N_j \ln \left(\frac{\theta_j}{x_j}\right)\right).$$

(11)

After applying Eq. (9) we get the alternative expression

$$\ln \left(\gamma_k^{\text{comb}}\right) = \ln \left(\frac{\theta_k}{x_k}\right) + 1 - \frac{\theta_k}{x_k} - \left(1 - \frac{z}{2}\right) r_k \ln \left(\frac{\theta_k}{x_k}\right) + 1 - \frac{\theta_k}{x_k}.$$  

(12)

This new expression for the SC-correction term no longer contains the number of nearest neighbors, $z q_k$, but the lattice coordination number times the number of sites, i.e. $z r_k$. Since Eq. (10) and Eq. (12) should yield the same activity coefficient for compound $k$, it follows

$$\left[\ln \left(\frac{\phi_k}{x_k}\right) + 1 - \frac{\phi_k}{x_k} - \frac{z q_k}{2} \ln \left(\frac{\phi_k}{x_k}\right) + 1 - \frac{\phi_k}{x_k}\right] = \left[\ln \left(\frac{\theta_k}{x_k}\right) + 1 - \frac{\theta_k}{x_k} - \left(1 - \frac{z}{2}\right) r_k \ln \left(\frac{\theta_k}{x_k}\right) + 1 - \frac{\theta_k}{x_k}\right].$$  

(13)

With Eq. (5) we can reduce and rearrange the above expression to a property $Q_k$, which is half the number of nearest neighbors

$$Q_k = \frac{z q_k}{2} = 1 - \frac{1 - \frac{r_k}{x_k}}{\frac{r_k}{x_k} - \frac{1}{1 - \frac{r_k}{x_k}}} = 1 - \frac{1}{1 - \frac{r_k}{x_k}}.$$  

(14)

This new relation tells us that $Q_k$ can be calculated from the mole, area and volume fraction, and that $z q_k$ is not a free parameter anymore, as it was considered in the original UNIQUAC model. In Appendix A we show that Eq. (14) yields a constant, despite the fact that it contains functions of mole fraction. It has clear similarity with relation 5, which can be rearranged to

$$\frac{Q_k}{z} = \frac{z q_k}{2} = 1 - \frac{1}{1 - \frac{r_k}{x_k}}.$$  

(15)

In order to apply Eq. (15) one needs either a reference area and a lattice coordination number, or a reference volume and area in order to calculate the relative volume $r_k$ and the relative area $q_k$, respectively. In the past this factor was obtained by setting $z = 10$ and by calculating $q_k$ using a reference area. We remark that the reference volume $V_{ref} = 25.17 \text{ A}^3$ was never changed after Abrams and Prausnitz [6] introduced it. The reference area, however, has been optimized several times in order to bring the activity models more in agreement with experimental results. Table 1 shows
several values for the reference area for different models, in which the SG-combinatorial correction term was implemented. In here the lattice coordination number was always fixed on the value $z = 10$, as was proposed by Abrams and Prausnitz [6].

We remark that with smaller values of the reference area, the number of nearest neighbors of a compound increases. This has little impact on the combinatorial term, but has large effect on the residual activity coefficient. In fact, the binary interaction parameter needs to be adjusted to lower values in order to keep the description of the experimental phase equilibria data in agreement.

### 2.2. Lattice independent UNIQUAC

Above it has been shown that choosing a reference area and a lattice coordination number is no longer required, and that Eq. (14) defines the combinatorial part of the activity coefficient model. Substituting Eq. (14) into the original combinatorial activity coefficient, Eq. (10), gives

$$\ln(\gamma_{k}^{\text{comb}}) = \ln\left(\frac{\varphi_k}{x_k}\right) + \ln\left(1 - \frac{\varphi_k}{x_k}\right) \ln\left(\frac{\theta_k}{x_k}\right).$$

(16)

The latter equation is referred to Vera et al. [17] as the restricted form of the UNIQUAC equation. However, we point out that Vera et al. [17] apply Eq. (15), while we use Eq. (14), which requires no definition of the reference area $A_{ref}$. We mention that in the limit $\theta_k \rightarrow \varphi_k$, the term between the square brackets becomes unity, and the Flory-Huggins equation is obtained. This also happens when we set $q_1 = r_j$, as this gives by Eq. (15) $r_j = q_1 = 1$, from which it follows that $\theta_j = \varphi_j$. The derived equation for $Q_k$ is also directly applicable in the residual part of the UNIQUAC model. It is noted that the residual part of the original UNIQUAC model contains an inconsistency. Instead of the frequently published equation, our analysis leads to

$$\ln(\gamma_{k}^{\text{res,UNI}}) = Q_k \left[1 - \ln\left(\sum_{j=1}^{M} \theta_j \tau_{jk} - \sum_{j=1}^{M} \frac{\theta_j \tau_{kj}}{\sum_{i=1}^{M} \theta_i \tau_{ij}}\right)\right].$$

(17)

This expression contains a factor $Q_k$ instead of $q_k$, which has been used in the original UNIQUAC model (see Appendix B). In Eq. (17) $\tau_{ij}$ denotes the Boltzmann weighting factor given by the contact energy of a lattice cell of compound $i$ and that of compound $j$

$$\tau_{ij} = \exp\left[-\frac{U_{ij}}{RT}\right].$$

(18)

The total activity coefficient for the lattice independent UNIQUAC model can therefore be expressed as

$$\ln(\gamma_{k}^{\text{UNI}}) = \ln\left(\frac{x_k}{\theta_k}\right) - Q_k \ln\left(\frac{x_k}{\theta_k}\right) + Q_k \left[1 - \ln\left(\sum_{j=1}^{M} \theta_j \tau_{jk} - \sum_{j=1}^{M} \frac{\theta_j \tau_{kj}}{\sum_{i=1}^{M} \theta_i \tau_{ij}}\right)\right].$$

(19)

The above principle holds also for the UNIFAC model. The difference between UNIQUAC and UNIFAC is that in the latter not molecules but molecule fragments are used as interacting entities in the residual part. Although UNIQUAC has been applied with success, we must not forget that the UNIQUAC model is based upon a first order approximation of the local concentration around a molecule in a mixture. This approach is accurate for systems having weak interactions, but for strongly interacting molecules the activity coefficient of the solute is underestimated. In that case the local activity instead of the local concentration of the solute should be used. This has been done in the COSMOSPACE [12] and GEQUAC [21] models.

### 2.3. Lattice independent COSMOSPACE

For a binary system, where each molecule can have two types of surfaces, the COSMOSPACE activity coefficient is expressed as [12].

$$\ln(\gamma_{k}^{\text{res,CS}}) = \frac{n_k}{2} \left[\frac{\varphi_k}{x_k} \ln\left(\frac{\gamma_{A,k}}{\gamma_{A,k}}\right) + \frac{1}{2} \ln\left(\frac{\gamma_{B,k}}{\gamma_{B,k}}\right)\right].$$

(20)

where $n_k$ is the total number of surface segments of molecule $k$, and $\gamma_{k}$ is the fraction of surface type $j$ on molecule $k$. The $x_k$ is used to define the fractions of the two components in the mixture and the pure state. We mention that in the original publication the total number of surface patches is calculated by the relative area as defined in the UNIQUAC model: $n_k = 2q_k$. Since we consider a fully occupied lattice, i.e., there are no empty cells in the lattice, the total number of surface segments on a molecule has to be equal to the number of nearest neighbors. That is to say, we do not subdivide the contact area into smaller patches, as is done in COSMOSPACE [11], because the patches of opposite segment sides make simultaneous contact, thereby averaging the interaction energy of the two contacting surface segments. Therefore we consider

$$n_k = 2q_k = 2q_k.$$

(21)

The variables $\gamma_{A,k}$ and $\gamma_{B,k}$ in Eq. (20) denote the activity coefficient of surface type $j$ in the mixture and the pure state, respectively. They can be calculated by

$$\ln(\gamma_{A,k}) = \ln\left[\frac{1 - \sqrt{1 + 4\theta_{A,k}^2 \theta_{B,k}^2 \omega}}{2\omega \theta_{A,k}^2}\right],$$

(22)

and

$$\ln(\gamma_{B,k}) = \ln\left[\frac{1 - \sqrt{1 + 4\theta_{A,k}^2 \theta_{B,k}^2 \omega}}{2\omega \theta_{B,k}^2}\right].$$

(23)

with $\omega = 1/\tau^2 - 1$ reflecting the interaction between the two different surface segments $A$ and $B$, and $\tau$ is the Boltzmann weighting factor of the COSMOSPACE model which is for weak

### Table 1

interactions related to the interaction parameters of UNIQUAC; \( \tau = \sqrt{\tau_1 \tau_2} \). In the limit \( \omega \to 0 \) the surface activity coefficients become unity, and the binary system becomes an ideal solution. The surface fractions of the two components in the mixture and the pure state are calculated by

\[
\theta_{A_2} = \frac{x_1 q_1^{\alpha A} + x_2 q_2^{\alpha A}}{x_1 q_1^{\alpha A} + x_2 q_2^{\alpha A} + x_1 q_1^{\alpha B} + x_2 q_2^{\alpha B}}
\]

and

\[
\theta_{B_2} = \frac{x_1 q_1^{\alpha B} + x_2 q_2^{\alpha B}}{x_1 q_1^{\alpha B} + x_2 q_2^{\alpha B} + x_1 q_1^{\alpha A} + x_2 q_2^{\alpha A}}
\]

The total activity coefficient of the lattice independent COSMOSPACE model can be expressed by the sum of Eqs. (16) and (20)

\[
\ln(\gamma_k) = \ln(\phi_k) - Q_k \ln(\phi_k) + Q_k \left[ \frac{\gamma_A^{\alpha A}}{\gamma_A^{\alpha A}} \ln \left( \frac{\gamma_A^{\alpha A}}{\gamma_A^{\alpha A}} \right) + \frac{\gamma_B^{\alpha B}}{\gamma_B^{\alpha B}} \ln \left( \frac{\gamma_B^{\alpha B}}{\gamma_B^{\alpha B}} \right) \right].
\]

3. Results and discussion

In this section we evaluate the accuracy of the renewed expression for half the number of neighbors, Eq. (14). For this purpose we chose binary mixtures of n-alkanes and 1-alcohols. Subsequently, we investigate how the UNIQUAC and COSMOSPACE models perform using the new definition for the number of nearest neighbors.

3.1. The number of nearest neighbors of n-alkanes

The calculation of the number of nearest neighbors by Eq. (14) for binary mixtures of alkanes between methane and nonacosane has been carried out for a series of 200 mol fractions between 0.001 and 0.999. Outside this range Eq. (14) suffers from computational inaccuracy due to the vanishing denominator, approaching zero. To calculate the volume and surface fractions in the binary mixture we used the van der Waals volume \( V_{vdw} \) and surface area \( A_{vdw} \) given by Bondi [22]. For n-alkanes Bondi gives the following relations

\[
V_{vdw} = \frac{6.88 + 10.23N_C}{0.6022},
\]

and

\[
A_{vdw} = \frac{1.54 + 1.35N_C}{0.06022},
\]

where we kept the original Bondi parameters and used the factors 0.6022 and 0.06022 to scale from molar size (cm²/nmol, and cm³/mol) to molecular area \( A^2 \) and volume \( A^3 \), respectively. As can be seen from the equidistant lines in Fig. 1, there is a clear linear relationship between \( z_{qk} \) and \( N_C \).

Methane, depicted at the bottom line, has a constant value for \( z_{qk} \) over the entire range from ethane to n-nonacosane. The same holds for the higher alkanes. The explanation for this is given in Appendix A. The open space in Fig. 1 represents the position of the pure liquid, to which Eq. (14) does not apply. However, since the values on the left and the right side of the open space are the same, it seems logical to assign this value as \( z_{qk} \) of the pure compound. This is an important observation, which we will use later. Based on the results depicted in Fig. 1, the relation between the number of nearest neighbors of the pure compound and the alkane number is given by

\[
z_{qk} = 4.87 + 4.27N_C.
\]

Sayegh and Vera [17,23] proposed the following empirical relation for the number of nearest neighbors based on an analysis of 15 classes of compounds

\[
z_{qk} = 0.4228V_{vdw} + 2(1 - I_k),
\]

where \( I_k \) is the number of internal contacts in a molecule and the van der Waals volume is expressed in cm³/mol. The empirical constant 0.4228 has the dimension mol/cm² and is equal to the quantity \( (z - 2)/V_{ref} \). We see that the value for the reference volume is dependent on the value of \( z \). E.g., if \( z = 10 \), then the reference volume is 18.92 cm³/mol or 31.4 A³/molecule, which gives \( A_{ref} = 48.2 A^2 \)/molecule, which is 20% higher than applied in the original UNIQUAC model (see Table 1). For n-alkanes, where \( I_k = 0 \), and using the van der Waals volumes defined by the van der Waals radii of Bondi, Eq. (30) becomes

\[
z_{qk} = 4.91 + 4.33N_C.
\]

This relation is close to Eq. (29). Although the van der Waals radii as proposed by Bondi are often used in the calculation of molecule dimensions, they are still matter of debate. We refer to the review article of Batsanov [24], in which it is argued that the van der Waals radii of Rowland and Taylor [14] should be considered as more reliable, because a much larger experimental XRD-data set has been used. The van der Waals radii of Rowland and Taylor for hydrogen, carbon and oxygen are \( R_H = 1.09 \) Å, \( R_C = 1.75 \) Å, and \( R_O = 1.56 \) Å, respectively. With these values and the Pauling bond lengths [25] the van der Waals volume and surface area can be calculated. Subsequently, using the same procedure as before, the number of nearest neighbors is obtained.
of Rowland and Taylor yields a parameter set of van der Waals radii. The set of van der Waals radii described in the section on n-alkanes, this leads to for the Bondi $R_k$. The number of nearest neighbors ($z_q$) of n-alkanes calculated by the original UNIQUAC formula. Comparing Fig. 2 with Fig. 3 it follows that the relation based on the van der Waals radii of Bondi is more in line with the alkanes with the same carbon number, as long as $N_\text{c} < 11$. This suggests that further optimization of the van der Waals radii is still needed. In fact, we expect that the slope of the number of nearest neighbors as function of the carbon number of the alcohols should be the same as that of the alkanes, because in both cases this only depend on the number of the CH$_2$ groups. Batsanov [24] indicated that the concept of spherical atoms in a molecule probably needs to be adjusted to ellipsoids, because the radius in the bond direction is smaller that the one perpendicular to it, which might also be important in a further refinement.

3.2. The number of nearest neighbors of 1-alcohols

Another class of linear molecules are the 1-alcohols. The required van der Waals radii of Bondi [22] and those of Rowland are (in Å): $R_H = 1.20$, $R_C = 1.70$ and $R_O = 1.52$, and $R_H = 1.09$, $R_C = 1.75$ and $R_O = 1.56$, respectively. Using the same method as described in the section on n-alkanes, this leads to for the Bondi parameter set of van der Waals radii. The set of van der Waals radii of Rowland and Taylor yields

$$z_{q_k} = 6.24 + 3.78N_\text{c}$$

(34)

$$z_{q_k} = 6.14 + 3.39N_\text{c}$$

(35)

Results of the various equations for $z_{q_k}$ of the 1-alcohols are depicted in Fig. 3. Like in the case of the n-alkanes, Eq. (14) gives for the alcohol mixtures lower values for the number of nearest neighbors than those calculated by the original UNIQUAC formula. Comparing Fig. 2 with Fig. 3 it follows that the relation based on the van der Waals radii of Bondi and Taylor are more in line with the expectation that the alcohols have more nearest neighbors than the alkanes with the same carbon number, as long as $N_\text{c} < 11$. This

3.3. The number of nearest neighbors of mixtures of n-alkanes and 1-alcohols

While $z_{q_k}$ of an alkane is independent of the other alkanes in the mixture, it becomes $N_\text{c}$ dependent when an 1-alcohol is added. Fig. 4 shows the case of n-hexane dissolved in an n-alkane and in a 1-alcohol. Although the number of nearest neighbors for n-hexane in a 1-alcohol does not vary with concentration, we observe that it becomes 1-alcohol dependent over a small range of $N_\text{c}$ values. When the carbon number of the alcohol is low, the number of nearest neighbors of n-hexane is slightly below the value of that in an alkane. In the case of Bondi’s set of van der Waals radii it even gives negative values when the difference in carbon number becomes smaller, which is unphysical. This artefact is caused by small errors in the calculation of the van der Waals volume and area, which is magnified by the denominator of Eq. (14). This artefact would also occur in the original UNIQUAC method, if the developers had use the right part of Eq. (15), instead of the applied $q/2$, for which an ad-hoc value of the coordination number ($z = 10$) and the reference area ($a_{\text{ref}} = 41.56 \text{Å}^2$) had to be defined. Above the carbon number of hexane the number of nearest neighbors approaches the pure component value. This makes sense, because the alcohol starts to increasingly resemble an alkane. The presence of an apparent singularity around molecules of equal size, however, demonstrates that the choice for a value of the number nearest neighbors is still a critical issue. In order to make the new expression for the UNIQUAC model applicable for all
types of solvent mixtures, we take the value obtained from the calculation of the compound in a mixture of molecules of its own class. This is equivalent to the number of nearest neighbors of the compound in its pure state. This choice implies that the coordination of other molecules in the first shell around a central molecule is set equal to that of the pure state.

3.4. The Staverman-Guggenheim correction term

We will now compare the combinatorial activity coefficient using the different expressions for the number of nearest neighbors and apply these to the binary system hexane - hexadecane.

Fig. 5 shows the comparison between the combinatorial activity coefficient of the different models and parameter sets for the binary system of n-hexane (1) and n-hexadecane (2). The activity coefficients of the Flory Huggins model, for which we used the original UNIQUAC parameters $r_1 = 4.5$ and $r_2 = 11.25$, are plotted as dashed curves, which end at the limiting activity coefficient values of $\gamma_1^{\text{comb,we}} = 0.729$ and $\gamma_2^{\text{comb,we}} = 0.558$. The different Staverman-Guggenheim models give curves which nearly coincide. The original UNIQUAC model, where $z = 10$, $q_1 = 3.86$ and $q_2 = 9.26$, gives curves that end at $\gamma_1^{\text{comb,we}} = 0.7404$ and $\gamma_2^{\text{comb,we}} = 0.5798$. The refined Staverman-Guggenheim model, i.e. Eq. (16) with $Q_k$ defined by Eq. (14), gives using the van der Waals molecular volume and area based on the radii set of Bondi: $\gamma_1^{\text{comb,we}} = 0.7380$ and $\gamma_2^{\text{comb,we}} = 0.5752$, while the set of Rowland and Taylor gives: $\gamma_1^{\text{comb,we}} = 0.7404$ and $\gamma_2^{\text{comb,we}} = 0.5798$. These values demonstrate that the difference between the original and the refined UNIQUAC models is negligibly small; less than 0.1%. This observation shows that the new equation for the number of nearest neighbors (Eq. (14)) gives nearly the same result as the equation used in the original UNIQUAC equation (Eq. (5)) for which a reference surface area had to be defined. Our approach demonstrates that the lattice model of UNIQUAC can be transformed into a fluid model without the definition of a reference area. This transformation is also observed in the Flory-Huggins model. Initially the number of lattice cells for each molecule was defined, but in the end the activity coefficient equation contains only mole and volume fractions, for which this definition is not needed. Likewise, the Staverman-Guggenheim correction requires the definition of the number of sites of each molecular surface, i.e. $z$, but this is later replaced with Eq. (14), and the activity becomes a function of mole, volume and surface fractions only. In other words, in both cases the concept of a lattice has served as a vehicle to reveal the dependency between activity coefficient and concentrations.

3.5. Activity coefficient models

3.5.1. UNIQUAC

In the theoretical section of this work (see Appendix B) we show that the residual part of the original UNIQUAC model contains an error. The correct derivation delivers a residual activity coefficient equation with $Q_k$ and not $q_k$ as molecular dependent variable.

Fig. 6 depicts several experimental isothermal vapor-liquid equilibria data and the UNIQUAC descriptions in three different ways: the original UNIQUAC model (dashed curves), and the lattice independent UNIQUAC model as given in Eq. (19) using Eq. (14). The optimized UNIQUAC interaction parameters Table 2.

The key quantity $Q_k$ is calculated by the volume and the surface area fractions defined by the molecular volumes and areas from Bondi’s (solid curves) and Rowland’s (dashed-dotted curves) set of van der Waals radii. We observe in Fig. 6 that the three different forms of the UNIQUAC model give equivalent descriptions of the vapor-liquid equilibria. The new equation somewhat overpredicts the pressure in the case of ethanol, and gives lower pressures in the case of pentanol. These deviations are not caused by the new expression, but by the combination of parameters and the first order approximation of the local concentration. This is more clear in the description of the binary n-hexane and ethanol, where all three models yield a heterogeneous azeotrope, while the experimental data show a homogeneous azeotrope. The exaggeration in pressure exists for all UNIQUAC models, but is more present in case of the lattice independent versions. The left plot of Fig. 7 shows that

---

**Fig. 4.** Results for $Q_k$ of hexane dissolved in alkanes (green dots/diamonds) and alcohols (blue squares/triangles) with Eq. (14) using Rowland’s set (solid curves) or Bondi’s set (dashed curves) of van der Waals radii. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

**Fig. 5.** Combinatorial activity coefficient $\gamma^{\text{comb}}$ of the binary n-hexane and n-hexadecane. Flory-Huggins model (small dashed curve, $\gamma^{\text{comb,we}} = 0.729$). The curves of the original UNIQUAC and the refined Staverman-Guggenheim models based on Bondi’s and Rowland’s set of van der Waals radii nearly coincide.
the lattice independent UNIQUAC models yield higher activity coefficients than the original UNIQUAC model; for hexane at mole fractions between 0.1 and 0.5 and for ethanol at mole fractions between 0.7 and 0.9. This difference between the two types of UNIQUAC models is caused by the small $q_k$ in the original UNIQUAC model versus the applied correct factor $Q_k$ in the lattice independent models; $q_{\text{Ethanol}} = 1.97$, $q_{\text{Hexane}} = 3.86$, and Rowland’s data give $Q_{\text{Ethanol}} = 6.48$ and $Q_{\text{Hexane}} = 12.85$.

The interaction parameters for the original UNIQUAC model are the smallest in value, followed by those of the lattice independent model based on Rowland’s and Bondi’s basis set of van der Waals radii. This is in line with the fact that the original UNIQUAC model uses the smallest value for the relative area, while in the refined models the van der Waals radii of Bondi give a larger molecular surface area than those of Rowland.

### 3.5.2. COSMOSPACE

In the article on the COSMOSPACE model [12] it was already made clear that poor results are obtained when the molecular surface of each compound is considered to be made of one type of surface. This so-called homogeneous surface approach fails, because in reality each interacting molecule, even an alkane, consists of at least two different types of surfaces. Therefore the most comprehensive form of the COSMOSPACE model is the so-called...
The non-homogeneous double-binary set-up is sufficient to demonstrate that Eq. (14) provides an accurate description for a series of vapor-liquid equilibria of hexane and an alcohol. For the description of the isothermal experimental vapor-liquid equilibria we have used two parameters: the number of nearest neighbors of the hydroxyl group \( n_{\text{OH}} \) in the alcohol and the alkyl-hydroxyl interaction parameter \( \tau(298) \) at the reference temperature of 298.15 K. An Arrhenius equation is used to define the interaction parameter \( \tau \) at other temperatures:

\[
\ln(\tau) = -\frac{\Delta E_{298}}{RT} = \frac{298.15}{T} \ln(\tau_{298}).
\]

where \( \Delta E_{298} \) is the interaction energy between the alkyl and the hydroxyl surfaces at 298.15 K. Simultaneous optimization of the isothermal vapor-liquid equilibria yields to a set of parameter values listed in Table 4.

Fig. 8 shows that the COSMOSPACE model gives an excellent description of the phase equilibria data. The two lattice independent COSMOSPACE models show hardly any difference between the results obtained with the van der Waals radii of Bondi and Rowland; the curves almost coincide. Statistical information in the form of the average absolute deviation indicates that Bondi’s set of van der Waals radii gives slightly better results than Rowland’s set (See Table 5).

In comparison to the UNIQUAC approach the COSMOSPACE model clearly gives a better quantitative description of the experimental vapor-liquid phase equilibria, especially the transition from heterogeneous to homogeneous azeotrope is captured well. This is caused by the better activity coefficient description in the mid concentration range as can be observed by comparing the two plots in Fig. 7. The description of the experimental data is best performed by the lattice independent COSMOSPACE model with Bondi’s set of van der Waals radii. With the number of contacts associated with hydrogen bonding, \( n_{\text{OH}} = 2Q_{\text{OH}} \), the change in pair interaction energy is calculated. The obtained values of 13.4, 18.6 and 18.9 kJ/mol indicate that the lattice independent model is closer to the energy of hydrogen bonding of alcohols (20 kJ/mol) than the original COSMOSPACE model.

In Fig. 9 we depict the prediction of the excess enthalpy of the binary systems n-hexane - ethanol at 40 °C [27] and n-nonane - ethanol at 25 °C [34], for which the parameters are taken from the vapor-liquid equilibria optimization. The prediction is qualitatively very good with respect to the location of the maximum.

The average absolute deviation of the predicted excess enthalpy is about 15% (see Table 6). This deviation is understandable from the fact that the induced dipole interaction between the alkyl parts of the alkane and the alkanol has not been taken into account in the calculations. It is expected that the inclusion of a dispersion term, as has been done in the DISQUAC [8,36], will improve the prediction of the excess enthalpy.

Fig. 10 shows the fraction of the number of nearest neighbors, \( \gamma_{\text{OH}} \), that acts as hydroxyl surface according to the optimization of the COSMOSPACE parameter \( n_{\text{OH}} \) and the total number of nearest neighbors \( n_k \) given by Eq. (34) (dashed curve) and Eq. (35) (solid curve). For comparison also the ratio in the van der Waals surface area of the –OH group and the total molecule are plotted. The van der Waals surface areas of the hydroxyl group are 24.3 Å² and 23.7 Å², for the Bondi and Rowland sets of van der Waals radii, respectively. The total van der Waals surface areas of the 1-alcohols are given by the linear relations for the Bondi and Rowland set of van der Waals radii, respectively.

\[
\Delta v_{\text{OH}} = 37.03 + 22.41N_C,
\]

and

\[
\Delta v_{\text{OH}} = 36.37 + 20.09N_C,
\]

We observe that the COSMOSPACE model gives lower values for the fraction of hydrogen bonding area, than is predicted by the ratio of van der Waals surface areas. This is logical because only a part of the hydroxyl van der Waals surface area is involved in hydrogen bond breaking. The original model overpredicts the surface area involved in hydrogen bonding, as a result of incorrect use of the $q_k$ parameter, instead of $Q_k$. This also explains why the incrementation of the hydroxyl group in the UNIFAC method failed for methanol, which would consist of one methylene group and one hydroxyl group. In UNIFAC the surface area of the strongly interacting part of the hydroxyl group was set equal to the van der Waals surface of the hydroxyl group. Extrapolation towards methanol would make it a strongly hydrophilic compound. Therefore methanol was defined as a new UNIFAC group.

4. Concluding remarks

We have shown that two expressions for the combinatorial activity coefficient can be derived from Guggenheim’s model for the entropy of mixing of linear molecules. These expressions yield a unique expression for the number of nearest neighbors of a molecule in a multicomponent mixture. This formula is a function of mole, volume and area fractions only, and makes a choice for the value for the lattice coordination number and the reference surface.

</table>
superfluous. In other words, in combination with the (revised) residual term as obtained for the COSMOSPACE model, it makes the total activity coefficient model lattice independent. We expect that the new formula also works for more complicated molecules, but this still needs to be verified. We have demonstrated that the new expression for the number of nearest neighbors leads to lattice independent versions of the UNIQUAC and COSMOSPACE models.

In order to put the various models in perspective, Table 7 shows a comparison indicating the lattice (in)dependency of the combinatorial and residual activity coefficients. In this table we use the label s-profi les, by which we indicate the whole procedure starting with QM-calculations, the averaging of surface charge densities of molecules and the collection of surface area into histograms. Hence, the three-dimensional lattice information vanishes in these conversions prior to the calculation of the surface and residual activity coefficients.

For the UNIQUAC model we first had to remove an inconsistency from the residual term of the UNIQUAC model in order to show this possibility. The original and the lattice independent version of UNIQUAC describe the investigated vapor-liquid phase equilibria with the same quality and accuracy as before. A much better description of these phase equilibria is obtained with the lattice independent version of the COSMOSPACE model. For 1-alcohols mixed with n-hexane at moderate temperatures it captures the transition from a heterogeneous to a homogeneous azeotrope when changing from methanol to ethanol. The number of parameters is substantially lower than those for the original and the lattice independent version of the UNIQUAC model. Especially for strongly interacting systems the lattice independent COSMOSPACE model is recommended above the UNIQUAC model.

The new formula gives a constant value for the number of nearest neighbors of a compound dissolved in a mixture composed of molecules of the same class. This value stays constant over the entire concentration range, except at limiting concentrations, where computational accuracy plays a role. Because the value of the number of nearest neighbors of a compound is independent from the other molecules of the same class in the mixture, one can assign this value as the number of nearest neighbors of the pure compound. This has shown to be a useful choice, because sometimes unphysical values are obtained. This happens when one of the compounds has nearly equal length as the compound of interest. Although this deviation is not significant for the combinatorial term, because the SG-term suppresses this by the $\phi_k/\theta_k$ term, it is not acceptable for the residual term. For the time being the proposed procedure for de ning the number of nearest neighbors works well as shown by the results in this work. It is hypothesized that the strong deviation is a result of Guggenheim’s entropy model, where a single lattice coordination number was used. It

In this appendix we demonstrate the usefulness of Eq. (14) by applying it to particular geometric cases.

Appendix A1. Chains of repeating units in a lattice

Lattices are in theory made out of space-filling structures. Table A.8 summarizes the volume and area of some space-filling structures as function of the number of units (N) in the chain structure. We also included the case of a chain of touching spheres.

Table A.8

In these expressions $L$ is the length of a side of the regular polyhedron, and $D$ the sphere diameter. The mole, area and volume fractions of mixtures of chains of one type of structure have the general forms

$$x_j = \frac{N_j}{\sum_{j=1}^{N} N_j}$$

$$\theta_j = \frac{s N_j^2 + N_j}{\sum_{j=1}^{N} (s N_j^2 + N_j)}$$

and

$$\phi_j = \frac{N_j^2}{\sum_{j=1}^{N} N_j^2}$$

where the parameter $s$, which denotes the quadratic contribution of the surface area, is 1, 2, and 5 for respectively, a tetrahedron, a cube, and a dodecahedron. Substitution of A.1, A.2, A.3 into Eq. (14) gives for Q

$$Q(N_k) = 1 + s N_k$$

which is concentration-independent. Eq. (A.4) proofs that for the calculation of the combinatorial activity coefficient of a mixture of space-filling chains, of which the beads are made of tetrahedra, cubes, or dodecahedra only, the Staverman-Guggenheim correction term is needed. For a mixture of chains of touching hard-spheres, the situation is different, as in this case the ratio of volume and surface fraction is always unity: $(\theta / \phi_j = 1)$. This implies that in Eq. (10) the Staverman-Guggenheim correction term becomes zero, and that only the Flory-Huggins term survives.
Appendix A.2. Linear and branched molecules

Eq. (14) was derived by using the connectivity relation of linear and branched structures. Here we show how Eq. (14) leads to expressions for the number of nearest neighbors as function of the number of repeating units. We start with a general formula for the volume and the area of a molecule containing \( N_k \) repeating groups and an end group.

\[
V_k(N_k) = V_0(1 + \alpha N_k),
\]

(A.5)

\[
A_k(N_k) = A_0(1 + \beta N_k).
\]

(A.6)

The constants, \( A_0 \) and \( V_0 \), define the size of the end group, while \( \alpha \) and \( \beta \) define the ratio of the volumes of a repeating group and the chain end group. Substitution into the equations for the volume and area fraction yield for mixtures that consists of molecules of one class

\[
\phi_k = \frac{x_k(1 + \alpha N_k)}{\sum_{j=1}^{M} x_j(1 + \alpha N_j)},
\]

(A.7)

\[
\theta_k = \frac{x_k(1 + \beta N_k)}{\sum_{j=1}^{M} x_j(1 + \beta N_j)}.
\]

(A.8)

As a result we obtain

\[
Q_k = \frac{1 - \phi_k}{1 - \frac{\phi_k}{\theta_k}} = \frac{1 - \sum_{j=1}^{M} x_j(1 + \alpha N_j)}{\sum_{j=1}^{M} x_j(1 + \beta N_j)} = \frac{\alpha}{\alpha - \beta} (1 + \beta N_k).
\]

(A.9)

This result explains why Sayegh and Vera [17,23] found a linear relation between the van der Waals volume of molecules and the number of nearest neighbors.

As an example we evaluate the binary propane-\( N \)-tetradecane calculation of the number of nearest neighbors using Eq. (14). According to Bondi’s table [22] propane has \( V_{vdW} = 37.57 \text{ cm}^3/\text{mol} \) and \( A_{vdW} = 5.59 \text{ cm}^2/\text{mol} \), and tetradecane \( V_{vdW} = 150.10 \text{ cm}^3/\text{mol} \) and \( A_{vdW} = 20.44 \text{ cm}^2/\text{mol} \). With these values we can calculate the volume and surface area fractions, and subsequently the number of nearest neighbors for each alkane by applying Eq. (14). The step-by-step results are given in Table A.9.

</tr>
</tbody>
</table>

The results of the other linear alkanes are shown in Fig. 1 of this work. Already with the two values from the above example we can write for the \( n \)-alkanes

\[
z_{q_k} = 64.68 + \frac{64.68 - 17.69}{14 - 3}(N_C - 14) = 4.87 + 4.27N_C
\]

(A.10)

This is equation (29) in this work. The above demonstrates that for a group of linear molecules there is a linear relation between the number of repeating groups \( N_k \) and the number of nearest neighbors \( Q_k \), which can be derived without the definition of lattice coordination number, a reference area and volume.

Appendix B. Corrected residual activity coefficient of the UNIQUAC model

The original UNIQUAC model contains some inconsistencies. In order to understand this we need to go back to the concept of Wilson [37], who stated that molecules in a fluid are not distributed randomly, but tend to cluster more around molecules for which they have a higher affinity. This leads to the concept of local composition. Within this concept the first shell around a central molecule has a different composition than the average concentration of the bulk. The local mole fractions of compounds 1 and 2 around molecule 1 and those around molecule 2 are defined by the quantities \( x_{11}, x_{21}, x_{12} \) and \( x_{22} \), respectively. A general expression for the local mole fractions \( x_{ij} \) follows from the situation where molecules are distributed randomly. This is certainly the case when the temperature is very high. We denote the temperature of the random case by \( T_{rs} \). In the random configuration all molecules are interacting with same, “random” interaction energy \( U_{ij} \). When we move molecule \( j \) from the random system to a system where it has a local configuration and interacts with central molecule \( i \) and energy \( U_{ij} \), the ratio of the 2 mol fractions can be quantified by the energy difference as

\[
x_{ij} = x_{j \text{exp}} \left( \frac{U_{ij} - U_{ij}}{RT} \right). \quad (B.1)
\]

Subsequently, the ratio of local mole fraction of molecules 1 and 2 around central molecule 1 can be defined as

\[
x_{21} \quad x_{2 \text{exp}} \left( \frac{U_{21} - U_{ij}}{RT} \right) = x_{21} \exp \left( \frac{U_{21} - U_{11}}{RT} \right). \quad (B.2)
\]

While Wilson implicitly assumed that all molecules have the same size, Abrams and Prausnitz [6] later took into account that the molecules are different in size and they used surface fractions instead of mole fractions. Hence the excess energy of mixing two pure compounds was defined as

\[
U^E = \sum_{i,j} z_i z_j [\theta_{ij}(U_{ij} - U_{11}) + N_{ij}\theta_{ij}(U_{ij} - U_{11})]. \quad (B.3)
\]

where \( \theta_{ij} \) is the local surface fraction of compound \( j \) around central molecule \( i \) in the mixture. We note that the factor \( z_{ij} \), i.e. the number of nearest neighbors, indicates that the quantity \( U_{ij} \) is the interaction energy between one side of compound \( i \) and one side of compound \( j \). Further we observe that the lattice coordination number is identical for all types of molecules; \( z_1 = z_2 = z \), which is set to 10 in the original UNIQUAC model. However, this approximation made by the developers of UNIQUAC is not necessary for the
residual part, as we will demonstrate below. In fact the approximation \( z = 10 \) made for the original UNIQUAC, is one of the root causes for systematic deviation in systems where molecules have a lower or higher coordination number. However, the approximation of \( z = 10 \) is not necessary, as we will demonstrate below. Let us first recall the quantity that denotes half the number of nearest neighbors of molecule \( j \). This is identical to Eq. (14), but now we also include the possibility that the lattice coordination number is different for each compound

\[
Q_j = \frac{z_j q_j}{2}
\]  
(B.4)

We mention that summation of this quantity equals to the total number of interacting pairs. With Eqs. (B.4) and (B.3) can be written as

\[
U^E = Q_1 N_1 \Theta_{21}(U_{21} - U_{11}) + Q_2 N_2 \Theta_{12}(U_{12} - U_{22}).
\]  
(B.5)

Here we implicitly assumed that the lattice coordination number of the pure compound is not affected by the mixture. Consequently we define the local surface fractions. In line with Wilson’s concept it means that we unpair from the random configuration one side of molecule \( j \) from one side of molecule \( i \), this involves energy \( U_{i,j} \), and pair the two in the local configuration where molecule \( i \) is the central molecule. This local configuration requires energy \( U_{i} \). Applying the same steps as in the Wilson model the ratio of the local and random surface fractions can be written as

\[
\frac{\Theta_{ij}}{\Theta_{ii}} = \frac{\theta_j}{\theta_i} \exp \left[ -\frac{U_{i,j} - U_{i}}{k_B T} \right].
\]  
(B.6)

This equation differs from the original UNIQUAC equation, where the factor \( 2/3 \) was used in the exponent. The quantity \( z \) can not be present in the exponent, because we place one side of a lattice cell from a molecule in random configuration in contact with one side of a lattice cell of the central molecule in the local configuration. The other cell sides of the molecule, which are also taken from the random configuration, can be placed to any other cell side, and do not take part in this calculation step! For convenience we define the interaction energy difference of unequal pairs and equal pairs on a temperature scale by

\[
T_{jk} = \frac{U_{i,j} - U_{i,k}}{k_B T}.
\]  
(B.7)

This gives the following two relations

\[
\Theta_{21j} = \frac{\theta_2}{\theta_1} \exp \left[ \frac{T_{21}}{T} \right].
\]  
(B.8)

\[
\Theta_{12j} = \frac{\theta_1}{\theta_2} \exp \left[ \frac{T_{12}}{T} \right].
\]  
(B.9)

The sum of the local surface fractions around a central molecule are unity, as imposed by the full occupancy boundary condition

\[
\Theta_{21} + \Theta_{11} = 1,
\]  
(B.10)

and

\[
\Theta_{12} + \Theta_{22} = 1,
\]  
(B.11)

from which follows that

\[
\Theta_{21} = \frac{\theta_2 \exp \left[ -\frac{T_{21}}{T} \right]}{\theta_1 + \theta_2 \exp \left[ -\frac{T_{21}}{T} \right]},
\]  
(B.12)

and

\[
\Theta_{12} = \frac{\theta_1 \exp \left[ -\frac{T_{12}}{T} \right]}{\theta_2 + \theta_1 \exp \left[ -\frac{T_{12}}{T} \right]}.
\]  
(B.13)

Substitution of Eqs. (B.7, B.12 and B.13) into Eq. (B.5) yields

\[
\frac{U^E}{k_B T} = \frac{Q_1 N_1 T_{21} \theta_2 - \theta_2 \exp \left[ -\frac{T_{21}}{T} \right]}{\theta_1 + \theta_2 \exp \left[ -\frac{T_{21}}{T} \right]} + \frac{Q_2 N_2 T_{12} \theta_1 - \theta_1 \exp \left[ -\frac{T_{12}}{T} \right]}{\theta_2 + \theta_1 \exp \left[ -\frac{T_{12}}{T} \right]}.
\]  
(B.14)

The Helmholtz energy is obtained from the integral

\[
\frac{A^E}{k_B T} = -\int_0^T \frac{U^E}{k_B T} \, dT.
\]  
(B.15)

Substitution of Eq. B into Eq. (B.15) gives

\[
\frac{A^E}{k_B T} = -Q_1 N_1 \ln \left[ \frac{1}{\theta_1 + \theta_2 \exp \left[ -\frac{T_{21}}{T} \right]} \right] - Q_2 N_2 \ln \left[ \frac{1}{\theta_2 + \theta_1 \exp \left[ -\frac{T_{12}}{T} \right]} \right].
\]  
(B.16)

Generalization of this binary case to a multicomponent system results in

\[
\frac{A^E}{k_B T} = -\sum_{j=1}^M Q_j N_j \ln \left[ \sum_{j=1}^M \theta_j \tau_{ij} \right],
\]  
(B.17)

where we defined

\[
\tau_{ij} = \exp \left[ -\frac{U_{i,j} - U_{i,j}}{k_B T} \right].
\]  
(B.18)

Using

\[
\ln \gamma_k = \frac{\partial A^E}{\partial N_k},
\]  
(B.19)

yields the correct residual term for the UNIQUAC equation

\[
\ln \left( \gamma^\text{res,UNIQUAC}_k \right) = Q_k \left[ 1 - \ln \left( \sum_{j=1}^M \theta_j \tau_{jk} \right) \right] - \frac{\sum_{j=1}^M \theta_j r_{kj}}{\sum_{j=1}^M \theta_j r_{0j}}.
\]  
(B.20)

The crucial point in the original UNIQUAC derivation is the incorrect use of the lattice coordination number to define the ratio of the local and random surface fractions. Both Kontogeorgis and Folas [38] and Klamt et al. [12] mentioned that the UNIQUAC equation was inconsistent and that the exponent required \( z = 2 \). This value is unphysical, because in a 3-dimensional system the lowest value is \( z = 4 \) (i.e. a lattice made of tetrahedrons). In a reply to the comment made by McDermott and Ashton [39] also Maurer and Prausnitz [40] elaborated on the UNIQUAC inconsistency. Their solution was to add a constant of proportionality \( c \) into the denominator of the argument of the exponential in Eq. (B.18). The value for \( c \) is mixture dependent, and has an average value \( c = 0.27 \).
This implies that the factor $z/2$ in the Boltzmann factor of the original UNIQUAC model was reduced from 5 to 1.4. The deviation from unity could be caused by the choice of $z = 10$ as well as the use of a fixed reference area $A_\text{ref}$ in the UNIQUAC model. But, as we have shown here, the origin for the aforementioned inconsistency and the need to use a proportionality factor to obtain better results lies in the incorrect definition of the ratio of the local and random surface fractions. The correct derivation leads to Eq. (B.6). This also eliminates the use of a single value of $z = 10$.
